HILE the writer is disposed to accept in the main e correctness of the now universal custom among genitourinary specialists of making urethroscopic aminations in nearly every case of urethral ease, he believes that there is a certain propor-n of cases which does not permit of such ex-ination; for instance, cases of suspected tuber-lous disease of the bladder or prostate, acute thritis, stricture, abnormally small meatus, etc. should be remembered, too, that not all patients ffering from genitourinary disorders seek the ll of the specialist, but it is the general prac-ioner whom they consult and trust for relief. e object of this paper is to call attention to a thod first introduced by Arthur Kollmann of ipzig, and which is known as the "Five-glass t." Kollmann employs this method as an ad-ional aid to urethroscopy in clearing up obscure es of urethral disease. Some five years ago, ile attending Kollmann's clinic as a "mitarbeiter," e writer was permitted to make a series of ob-vations regarding the value of this procedure a diagnostic measure, and it is now his desire publish the histories of a few cases occurring in ivate practice in which this method proved of eat assistance in reaching a correct diagnosis.

Scientific urethroscopy requires long study. A rtain amount of constant practice is necessary interpret the nature of the lesions as revealed by e urethroscope, and not all practitioners possess ethroscopes, nor have they the time to devote order to attain the proficiency required of the ecialist. The method about to be described simple and, for all practical purposes, efficient. is not recommended as an equal of urethroscopy, t as an aid to the general practitioner. The equisite articles are as follows: a syringe of about ix ounces capacity, a hard rubber catheter, and five ordinary urine glasses. The catheter should be one having its eye as near to the point as possible, otherwise errors are likely to occur. This will be explained later more in detail. The principle of the operation is simply the thorough cleansing of the anterior urethra, and then allowing the patient to urinate into three glasses. The advantage of this method over the old Thompson two- and three-glass test is obvious. We are certain that the anterior urethra has been freed from shreds and mucus, and that any of these elements appearing in the urine must come from a point behind the external sphincter.

Modus operandi: The patient is instructed to call at the office early in the morning and to retain the night's urine until the physician has thoroughly cleansed the anterior urethra. After cleaning the meatus with some antiseptic solution, the physician introduces the catheter up to the external sphincter, care being taken not to force it beyond this point. Steadying the catheter in this position by grasping the penis with the left hand and holding the catheter by the forefinger and thumb of the same hand, the physician attaches the syringe filled with a mild boric-acid solution, and gently forces the fluid into the urethra. The returning fluid is allowed to fall into a urine glass held by the patient. The physician examines this and notes the presence of shreds and mucus. After detaching the syringe, it is again filled and the irrigation repeated. All the solution returning from the urethra is poured into one glass and is known as No. 1. The irrigation is continued until no more shreds are found in the irrigating fluid. Ten to fifteen irrigations may be necessary before this result is reached. When the physician is certain that he has removed all shreds present in the anterior urethra, he allows the fluid returning from the last injection to remain in the glass held by the patient, and designates this as No. 2, or the "control glass." The catheter is then withdrawn and the patient is permitted to urinate into the remaining three glasses, numbered respectively, three, four, and five. Glass No. 3 should always be regarded as doubtful, since it is possible that some shreds in the anterior urethra did escape the irrigation. Shreds in glasses No. 4 or 5 signify pathological changes in the posterior urethra, bladder, and possibly kidneys.

A convenient schedule in preserving results of such examinations is appended herewith:

	I	II or control	III	IV	V
Normal	shreds or clear	clear	clear	clear	clear
Anterior urethritis	shreds	cle r	clear	clear	clear
Anterior urethritis	shreds	clear	shreds	clear	clear
Ant. and Posterior urethritis	shreds	clear	shreds	shreds	shreds or clear
Posterior urethritis	shreds or clear	clear	shreds	shreds	shreds or clear

Possessing such schedule, the physician need but note below each column the conditions found, thereby having at a glance the result of the test.

Possible errors: As pointed out by Wossidlo (Die Gonorrhoe des Mannes und ihre Komplication, Berlin, 1903), a tight meatus may interfere with the proper performance of the test, by hindering the return flow of the irrigating fluid, and thus forcing it through the external sphincter. Of course, under such conditions, the results are worthless. Attention has been called to the absolute necessity of employing a catheter with its eye situated as near to the tip as possible. This is imperative, otherwise there would be an area of the urethra—that portion extending from the spincter to a point corresponding to the situation of the catheter's eye—that would not receive the play of the irrigating fluid. For this reason, it is a good plan to turn the

catheter with each injection, in order that no part of the urethra escape the injected fluid.

The test is completed by making microscopical examinations of the morphological elements found in the irrigating fluid and in the urine. Shreds from the anterior urethra are composed of long twisted threads or rolls of epithelial cells, pus cells, and mucus. These epithelial cells are usually of the flat variety. The pus cells may or may not contain gonococci. Filaments from the posterior urethra are simply particles of the secretion which are contained in the ducts of the prostate gland, and which have been pressed out by the contraction of the muscular tissue; they are somewhat shorter and thicker than those from the anterior urethra, and usually sink rapidly to the bottom of the glass. Epithelial cells from the posterior urethra are of the transitional type, and are difficult to differentiate from those of the bladder. The epithelium of the bladder resembles in its character that of the ureter, namely, transitional stratified. According to Bizzozera, the type of the cells from the pelvis of the kidney, ureters, and bladder are identical. These cells are usually smaller than those from the anterior urethra, are of a polygonal or elliptical shape, and contain a large nucleus. The protoplasm is markedly granular. Von Jaksch differentiates their origin as follows: small numbers speak for the ureter; moderate numbers, and lying like the tiles of a roof, indicate the presence of a pyelitis, while large groups of cells signify bladder desquamation. He adds, however, that this method should not be regarded as an absolute guide in diagnosis, but should be considered with other symptoms. Blood cells in one or the other glass will indicate from what part of the urethra or bladder, hemorrhage ensues.

The following three cases, taken at random from my private case-book, attest the value of this method:

Case I.—S. H., æt. thirty, single, shipping clerk, came to me January 7, 1900, for treatment. He related the following history: On September 1, 1899, five days after exposure, he detected an urethral discharge. His physician ordered injections of a solution of permanganate of potash and some internal medication. At the end of five weeks, the discharge ceased, but reappeared about a month later. The old treatment was resumed and continued for several weeks, and, the discharge having ceased, the patient was regarded as cured, notwithstanding the persistence of a glairy discharge. When he came under my observation the status was as follows: Urethral discharge containing few pus cells, no gonococci. Prostate slightly enlarged and moderately sensitive. Urine contained numerous shreds, a few of which were examined, and found to contain pus cells, epithelial cells, no gonococci. The patient was ordered to call again the next morning, and was directed to retain the night's urine. Kollmann's test: Ten irrigations were necessary to clear the anterior urethra of shreds. Glass No. 3 contained one shred, Nos. 4 and 5 none. Microscopical examination of these shreds proved desquamation occurring in the anterior urethra. Treatment: Regular dilatations with Kollmann's anterior dilator, and occasional irrigations of the anterior urethra with a 1-1000 silver nitrate solution. Patient cured in eight weeks.

Case II.—G. B., æt. forty, called to see me during the latter part of 1900 with the following history. The first of several attacks of specific urethritis occurred in 1895, and two years later the patient began to experience difficulty in micturating. The difficulty increased until 1898, when, after an attack of retention, he consulted a physician, and was treated for stricture. This was followed by relief for two years, but after that the old symptoms of stricture returned, increasing up to the time of his call at my office. Status: Strictura urethræ, four inches from meatus, admitting only a No. 7 French bougie. It is long, dense, and is readily felt by the finger. The patient passes water spasmodically; urine contained shreds. Treatment: stricture divided by means of Kollmann's urethrotome. Subsequent to this, regular dilatations made. At the end of three months it was possible to introduce a No. 25 French sound. Urine still continued to contain shreds. A Kollmann's five-glass test was made, the result of which showed a chronic posterior urethritis. Posterior dilatations were made with the curved dilator. Regular instillations with a solution of nitrate of silver were made into the posterior urethra, and the patient discharged cured six months after his first visit at the office.

Case III.—L. M., æt. twenty-five, single, came to me on the morning of July 1, 1899, complaining of a severe hemorrhage from the urethra. He was bleeding profusely and confessed to having indulged in excessive coitus the night before. He did not notice the bleeding until a short time before calling at the office. Treatment: a good-sized catheter was introduced into the bladder, and retained there with a moderately tight bandage wrapped around the penis. Salol in five-grain tablets were ordered to be taken six times a day. The patient was put to bed. At the end of four eight hours the catheter was removed, cleansed, reintroduced. Two days later it was again withdrawn. There being no more bleeding, it was reintroduced, but the patient was directed to call again in a few days. Several days later the patient presented himself at the office and complained of passing bloody urine. He was told to return the next morning, and instructed to retain the night's urine. This he did, and I found on examination a slight amount of blood issuing from the meatus. This may have been sufficient to indicate the site of hemorrhage as being situated anterior to the external sphincter. The Kollmann test was tried nevertheless, and proved conclusively that such was really the case, since the urine passed after thorough cleansing of the anterior urethra was free from blood. A week's rest in bed, cold applications, to the parts, and allowing the soft rubber catheter to remain in the urethra for several days at a time, relieved the patient. Sounds were passed occasionally and the patient discharged about two weeks after the receipt of his injury.

In conclusion, the writer desires to express his gratitude to Dr. Arthur Kollmann for the permission to make in his clinic a series of observations regarding the value of this diagnostic measure, and which have prompted the publication of this article.

304 Second Avenue.

Intestinal Exclusion.—According to Hartmann, indications are: The relief or cure of (1) strictures new growths of the intestine; (2) chronic inflammatory lesions which it is hoped to cure by diverting the fæces so giving rest to the inflamed part; (3) artificial anus fecal fistula; (4) fecal fistula secondary to abscess; intestinovaginal fistula; (6) chronic intussusception; congenital obliteration of the bowel (rarely practical (8) severe and intractable colitis. The forms of operation may be: (1) Enteroanastomosis or short circuit (2) Operations in which the diseased portion is completely excluded by section of the bowel above and below disease. (3) Operations in which only one section is re —*Gazette des Hôpitaux.*

ANTISTREPTOCOCCIC SERUM IN THE TREATMENT OF SMALLPOX.

By ALFRED C. SMITH, M.D.,
BROWNSVILLE, PA.

I WISH to call the attention of the profession to the successful use of antistreptoccic serum in

FIG. 1.

treating a series of cases of smallpox within the last three months, as follows:

CASES I and II.—Two boys, aged respectively three and fourteen years. The older had been unsuccessfully vaccinated and the younger had never been vaccinated.

I could not find the time of exposure, as there had been a case or two, next door, for several weeks. They were both in the initial fever of smallpox at the date of the first visit.

The eruption appeared two days later, September 28, and the following morning injected each with a full dose (20 c.c.) of antistreptococcic serum, repeating the dose the next morning, with the result that the fever subsided; the eruption came out well in both cases, the older being the confluent form, following the characteristic stages of macula, papula, vesicle, to the point of umbilication. Then, instead of the loathsome pustule, with its attendant secondary fever and the serious consequences of septic absorption, a complete cessation of symptoms and no pus formation, with a rapid drying of the vesicles, with an almost perfectly smooth skin resulting, there being no pits and the superficial redness of the skin cleared rapidly and the cases were released from quarantine in seventeen days.

Two doses of serum (20 c.c.) were administered in each case (see the illustrations, taken at height of vesication and ten days later, showing superficial scars but no pits).

In the house at the time of the outbreak there were three susceptible persons, all of whom were protected by immediate vaccination, successfully performed.

CASE III.—Colored woman, aged forty-two. Called November 1 to find the initial period had been in progress for the past six days, and the papules were well formed on the hands and face in large numbers. Injected the serum, repeating the dose the following day, to have full vesication follow, but no pustulation nor secondary fever, and a rapid desiccation of the diseased cuticle and healing without any pitting, with perfect recovery at the end of twelve days, with release from quarantine on the fifteenth day of treatment.

CASES IV and V.—Babe, ten months, and boy, four years, taken at the same time, November 23. I used the serum at once. The eruption appeared the following day, one discrete, the other confluent, one of the worst that I have treated in a series of ninety-one cases, having a hemorrhagic tendency. After vesication was complete, there was at once a diminution of the swelling, no pustulation, and at the end of ten days the crusts were loose and the greater part of the skin had peeled off, as the entire cutaneous surface was involved, yet not the slightest indication of lung or kidney involvement, which was expected.

CASE VI.—Colored girl, aged eleven years. I was called December 13 to find the eruption well out in the papular stage, with four susceptible persons in contact with the patient, all of whom were successfully vaccinated at once. The patient received a 20 c.c. dose of serum, repeating in eighteen hours, to have the vesicles form two days later, which were shrunken flat in forty-eight hours after vesication was complete, without the

FIG. 2.

least pus formation three days after the serum injection. The only crusts were on the nose, where the sebaceous follicles were involved.

At the end of fourteen days the body surface was clean and smooth, covered with the superficial scars, but no pitting. The eruption was pro-

nounced, and where the garter encircled the leg the vesicle extended entirely around.

The other medicinal treatment used was only mild laxatives of calomel et sodium bicarbonate with sponge baths of 1-4000 bichloride mercury solution, with hot bath of the same when desquamation was ripe. Used no masks nor emollient protectors, yet had no pitting, nor did we have itching to any marked degree. I have seen in these cases none of the general debility that followed the disease in former cases in which the treatment was by the usual drugs and antiseptic washes, though the same has been successful, as I had only one death in a series of eighty-three cases, but in most I have noted tedious convalescence and affected health following recovery. Thus by the serum treatment we have a shortening of the duration of the disease, absence of the secondary fever, lack of absorption of septic products by prevention of pus formation, no pitting, no marked debility, less suffering, and much less danger of lung and kidney involvement, with a much more rapid convalescence.

In conclusion, I will say that it is to be regretted that the profession is so slow to give the patients the benefit of these life- and suffering-saving means that science has placed at its disposal. One great mistake made in the administration of any of the serums, is too long delay and insufficient quantity used. Use it early and in sufficient quantities to command a complete neutralization of the toxins it has to counteract.

IMPORTANCE OF TREATMENT IN THE EARLY STAGES OF ARTERIAL DEGENERATION.

By LOUIS FAUGÈRES BISHOP, A.M., M.D.,
NEW YORK.
ATTENDING PHYSICIAN, LINCOLN HOSPITAL.

The term degeneration of the arteries is a better term than arteritis, arteriosclerosis, or endarteritis, because it is less definite and can be made to include functional as well as material vices. This condition is the result of the many causes which act in opposition to the tendency of life to go on without loss of quality or impairment of power—in other words, it is the failure of repair and the failure in the action of the mechanism for the automatic correction of irregularities in the circulation.

The light thrown upon this condition by pathology is extremely unsatisfactory because we often find a most extreme arterial sclerosis without marked symptoms, and we find marked symptoms with hardly appreciable physical changes. The degeneration of function is more striking during life than degeneration of tissue. So long as we have to deal then with living people, the perfection or otherwise of the processes of life is the important element. This element is entirely beyond the view of the microscopist.

The failure of circulation may be due to functional causes as much as to a condition represented by appreciable structural change. The teaching of modern science has been too much in the direction that phenomena can be wholly explained by structure. This is not true of the working mechanism of the human organism, nor indeed is it true of even mechanical things.

I was much struck recently by a description of his own case as given by a gentleman who has achieved success in life through the able manner in which he has managed a railroad. He is suffering from a cardiac circulatory failure and said: "I think I am like one of the old engines on my railroad—about ready for the scrap-heap. You may be able to patch me up and keep me going for a little while, but you cannot make me new again." He said that when an engine first came out of the shop it could do two hundred miles a day and at the end be just as good as at the start. After a while there would be a little leak in one of the valves and it would have to go to the shop to be repaired. Later on another valve would leak and then there would be trouble with the fire-box. When this once began, though each time the engine came out of the shop it would appear to be all right, it would always be going back again, and at the end of a hundred miles one might always expect something to be wrong. He said further: "I employ a master mechanic to overhaul the engines every morning, and in this way we manage to keep them going, even though they are old; but there always comes a time when repairs do not pay, and then they are sent to the scrap-heap." This was a simile more true than pleasant.

There is something about a piece of machinery that has borne the stress of hard usage that is very like the behavior of the human body under the same conditions. It pays in the long run to buy new machinery, and it would certainly pay to get a new body if that were possible. A new automobile can be managed and kept running by one of little experience, but to keep an old one running requires the knowledge of an expert.

Machinery can be replaced, but for the human being there is only one body as far as we know, so we must make the best of it. For this reason the study of the repair of the failing human organism and the discovery of all those methods by which it may be kept smoothly running are well worth our best efforts.

The human organism is a much better machine than any invented by man. It has within itself arrangements for the repair or concealment of the earlier manifestations of many serious affections. In a way this is a disadvantage, because the earlier signs of degeneration are only to be detected by the trained perception of a skilful observer. This is particularly true of the circulation. The earliest sign is an irregularity of tension in the arteries and this goes on to a pretty constant high arterial tension. The inherent forces conceal the defect whenever they can and bring about a compensatory hypertrophy of the heart.

This is the time when it is a pleasure and satisfaction to the physician to step in and by proper régime and treatment regulate the arterial disorder and the causes which are leading to it. Once in a while there is a patient who will submit to regulation before the appearance of conscious symptoms. The great majority of such cases have come under my care only at the stage when the hypertrophied heart, having wearied of the burden of maintaining the high arterial tension, has become feeble and probably dilated. Such was the case of the patient who compared his state to that of the broken-down motor. He presented the picture of cardiac failure—the heart dilated, with blowing murmurs, a feeble and irregular pulse, shortness of breath on the slightest exertion, albuminuria, and anæmia. It was a case in which medical aid was sought only after the reparative powers of the body had exhausted themselves. Two, or even one year earlier, the process might have been checked, so that the scrap-heap's day would have been much longer postponed.

To make an estimate, which must be purely a guess, the expectation of life is in inverse proportion to the postponement of treatment after the earliest signs of irregularities of arterial tension due to the changes of degeneration.

LAPAROTOMIES ON ONE PATIENT.

By HOWARD CRUTCHER, M.D.,
CHICAGO.
ING SURGEON TO THE CHICAGO & ALTON RAILWAY COMPANY.

)4 Mrs. B., American, aged twenty-nine years, ɔd, no children, with a history of gonorrhœa yphilis, sent her husband for me, with the ge that she was suffering terribly with inflam- n of the womb and bowels, and requested come at once. I got to her bed side about o'clock in the afternoon and found pretty efined indications of a pelvic abscess. While ıg the examination, whether from my fault , I distinctly felt the mass collapse, and urged ımediate operation. Two hours later, on ıg the abdomen, the pus from an enormous abscess was found to have been well distri- over the peritoneal cavity. Abundant flush- ree drainage, and a very unfavorable prog- were promptly given.

ı got well, but some months later developed a ıl hernia, which she wanted removed. The l operation was carried out without incident y of note, and the hernia was cured.

'.a year or so I lost sight of the patient, ne day received word that the uterus and ı were again the seat of inflammatory troubles, ı prompt call was requested. This time an bted appendicitis was found, with symptoms rforation. An immediate operation was med, a gangrenous appendix with two per- ns removed, and the abdomen drained. I to say that on account of the old tubal dis- I opened the abdomen in the median line, g that I was not altogether right in my diag- as to the appendix. She promptly got well.

1896 she came to my office with the startling that she was "growing a tumor." I per- d her to give the tumor a chance for a time, she did. Some months later she returned that she had been taking some form of absent ent from some quack, and that she feared hing more direct was now demanded. After nation I agreed with her. Another median n, the removal of a three-pound ovarian and the careful closure of the abdomen were atures of this operation. I may say that the ovary had been removed at the time of the operation. This time she made the usual recovery.

1898, following the nerve-racking newspaper s of that eventful year, Mrs. B. developed r tumor. Before making an examination I her that I was at some loss to recall any tissue which a tumor could grow. Examination nly disclosed a growth of some character in lvis. Operation was deferred for a time, but ondition growing worse, I opened the abdo- for the fifth time, and found two diffuse intra- entous cysts, each very extensive, and not ting of proper removal. The left cyst con- dark-colored fluid resembling black coffee, s the right gave out clear, limpid fluid with- trace of coloring. About forty ounces came each side. The cyst walls were stitched to ritoneum, and the cavities were well packed gauze. The cysts were obliterated by this ent and the patient soon got on her feet.

ut a year following the fifth operation she returned with another ventral hernia. No er! Of course she was firmly determined to it cured by operation. I told her that I had ed never to perform half a dozen laparoto- on one patient; that the town was full of am- us operators, and that she must seek other services than mine. I learned later that she had returned to the ranks of the faith healers, who promptly convinced her that she was free from all bodily ailments, which of course rendered further operative measures unnecessary.

COLUMBUS MEMORIAL BUILDING.

OUR RURAL WATER SUPPLIES.

A WORD FOR THE THOUGHTFUL.

By HARVEY B. BASHORE, M.D.,
WEST FAIRVIEW, PA.

THERE has been a great revival lately in regard to public water supplies, and cities are spending immense sums in the construction of sanitary water works. All this is very desirable, but there is another water supply—that of the rural population—which has been receiving scarcely any thought or attention. Though this rural population may seem rather insignificant, yet it comprises, according to the last census, just about 70 per cent. of our people—varying from 20 per cent. in some of the New England States to 95 per cent. in some of the Western States. In other words, something like 40,000,000 of people in the United States simply take the water most available in an economic way—the sanitary availability in these instances being an unknown factor.

Though these rural drinking waters come from many different sources, individual wells, springs, and small streams scattered through the country, it has been found that they are very similar in one respect, namely, in their utter unreliability for furnishing a suitable drinking water. Whether we take it in Canada or in Florida, in Pennsylvania or in California, this unfitness of the rural drinking water is a striking feature.

Unfit, you say, yet our fathers drank this very water and lived to a good old age. But we must not forget that every year of habitation increases in a geometrical ratio the dangers of soil pollution surrounding that habitation, and though our fathers did drink a pure water, there surely comes a time when we cannot do so from the same well or spring, unless proper precautions have been taken to keep the water undefiled. These, to be sure, are broad assertions, and in view of such the sanitary skeptic may well question the *seeming* health of the rural population.

Though the mortality statistics in the country are very meager, we yet have enough to show that the country population is not as healthy as it seems, and while in every place the rural death rate is lower than the urban death rates, yet the lowering in the country has not been as great as in the cities, and in some localities the rural annual death rate is actually increasing, other conditions, of course, remaining the same.

When we come to examine the typhoid statistics we find that while the death rate of other diseases is generally much lower in the country districts than in the great cities, the prevalence of typhoid fever in the country is almost always equal to, if not greater than, that in the adjoining cities. In several instances reported, the rural typhoid rate is even ten times greater than the urban rate in the same district. With a scattered population such as exists in the country, facts like these are often overlooked and unsuspected until attention is called by actual records.

We have been hearing for a number of years of the deadly scourge of typhoid fever that has been ravaging the city of Philadelphia, and enough has been written about it to pay for good-sized water works. Such is the case when statistics are kept and published.

Now shift the scene to one of the beautiful valleys of Central Pennsylvania, made up entirely of a rural population, with only one hundred (100) inhabitants to a square mile—a region of fine farms, wild mountains and woods, a place of country residences and picnic groves, and this ideal happy valley, than which it is hard to imagine a better, has had just as much typhoid fever, in proportion to population, as the great city itself; yet no one suspected that such a condition existed, and even now the inhabitants themselves would scarcely believe it, but the record is a true one, and I believe that many other places would show results not a whit better if the real facts were only known.

The worst part of the story is that there is no remedy easily available for this condition. In the urban supplies there are only a few sources at the most, and the municipal government can readily control the conditions affecting the water supply of its citizens, if it so desires; but what of the remedy when the sources of supply are numbered by the thousands? It would take an army of chemists and a mint of money to give the same supervision to the country well that we give to the metropolitan supply.

The only remedy at present seems to be in the rapid education of the people to the point that each citizen will learn what pure water is, how to obtain it, and how to keep it pure, and this rests mainly with the medical profession and with the press. A thankless task it may seem—a crusade for pure water in the country, yet the glory in achievement in saving lives and human suffering would well repay the labor.

A RADIOGRAPHIC SURPRISE.

By W. I. LeFEVRE, M.D.,
CLEVELAND, OHIO.

The patient, a young woman, was sent to me by Dr. Romig of East Cleveland to have a radiograph taken to locate a needle which she had run into

her foot when a child. For several years past she had suffered pain in the foot, this at times being so severe she could scarcely walk. It seemed to be growing gradually worse, so she determined to have the needle removed. Upon developing the plate, however, a distinct osteoncus was discovered at the exact point of pain, the needle being embedd a short distance away. The plate also showed second exostosis upon the lower side of the fi metatarsal bone. The tumors were removed.

Foreign Medical Practitioners in Italy.—The questio the legal status of holders of foreign degrees or diplo who wish to practise in Italy came again before the It Legislature in December. Dr. Santini, the leading s in the recent agitation to preserve Italy for the Itali asked a question on the subject. Signor Giolitti, the M ister of the Interior, said the existing law allowed for doctors to practise their profession in Italy when they called in to advise in special cases, or when they under the charge of foreign patients exclusively. If such p titioners attended Italian patients, that was an a which the Government would do its best to supp With regard to reciprocity he promised without dela enter into negotiations on the matter with such fo countries as did not grant equivalent privileges to It practitioners. He added, however, that foreign p tioners were not sufficiently numerous in Italy to their competition a serious matter for Italian grad Signor Orlando, Minister of Public Instruction, state he would admit to the examinations of the Italian ties only foreign practitioners who had pursued studies in universities of good repute, recognized medical faculties and the Superior Council of Instruction.—*British Medical Journal.*

Contribution to the Study of Natural Immuni Turro presents the following conclusions: (1) Ovis the product of the solution of the yolk of the hen's the white of the same. In a period of from twenty to a month, it acquires in vitro a bacteriolytic po great that it digests the fourth part of its weight culture of Bacillus anthracis without exhausting its ac which is preserved for a second or third digestion. The subcutaneous injection of from 5 to 10 gr. of ovi in a number of rabbits, repeated on three conse days, and the inoculation on the fourth day of a d pustule virus, hastens the death of the animal; b injection of 5 gr. to a kilogram at one time, and the lation of virus 10 or 12 days after the injection, r the death of the rabbits from nine to seventeen days. The intravenous injection of 5 gr. of oviserum dilute 45 gr. of distilled water determines the same effects. mata of 10 gr. of oviserum in 40 gr. of water reta onset of bacteriæmia according to the condition in they have been absorbed. (4) The doses of 5 gr. of rum to a kilogram of rabbit suffice to bring abo delay indicated; a larger dose does not augment it; 50 retard the death from five to nine days; 1 gr. do produce a clearly appreciable effect. (5) When th mal functions of the rabbit injected with 5 gr. of ovi are disturbed during the period of physiological which exists between the injection and the inoculat the virus, the immunizing action of the oviserum dec or is annulled. The immunizing action of the ovi does not manifest itself till the time that it is assim by the organized plasma. Its bacteriolytic power, by means of a physiological synthesis to that of the a which the plasma has contained since birth, seems the cause of the great resistance that the rabbits ac to the pustule virus. (7) The splenic pulp macerat one per cent. saline solution brings about in the ra effects analogous to those of the oviserum. (8) The i tion of 50 gr. of saline solution of 7.50 per cent. to a gram of rabbit (and inoculation of a drop of pustule v at the end of twenty-four hours) retards the death of rabbits from ten to fourteen hours. The injection of gr. and the inoculation of the virus at the end of twe four hours determines an extraordinary phenomenon. rabbits do not die of bacteriæmia. The action of saline solution is fleeting; it disappears in from on three days.—*Archives Latines de Médecine et de Biol*

LATE EFFECTS OF TYPHOID FEVER ON THE HEART AND VESSELS.

R. W. S. THAYER, Associate Professor of Medicine in the Johns Hopkins University, has published in the American Journal of the Medical Sciences, for March, a series of observations made by him, being part of a study of the cardiac and vascular complications and sequels of the cases of typhoid fever treated in the past fourteen years in the clinic of Professor Osler, in Johns Hopkins Hospital. These observations, although not quite complete, have been carefully and even elaborately worked out, and give a clear idea of the condition of the heart after typhoid fever.

Dr. Thayer summarizes the result of his studies as follows: (1) The average systolic blood-pressure in these old typhoids was appreciably higher than in control observations upon healthy individuals. (2) The higher average of the blood-pressure was constant in every decade. (3) In many instances among the old typhoids the blood-pressure exceeded appreciably the limit of what is usually regarded as normal. (4) The radial arteries in the old typhoids were palpable in a proportion nearly three times as great as that found in control observations upon supposedly healthy individuals who had never had any disease. (5) The average size of the heart was greater among the old typhoids than in the same cases at the time of admission to the hospital. The difference held good also when the cases were classed according to age by decades. (6) Cardiac murmurs were heard with considerably greater frequency among the old typhoids and in the same cases during the attacks. (7) In eight cases in which, on discharge from the hospital, the heart was consider normal, subsequent examination revealed hypertrophy, with mitral insufficiency. One case showed a possible mitral stenosis; one an aortic insufficiency; one a picture general arteriosclerosis, with hypertension. (8) In one case an aortic diastolic murmur was present four months after discharge, but had disappeared five months later. (9) Those patients whose pulse during the disease was remarkably rapid or irregular, showed, in general, on later examination, a blood-pressure above the common average for the old typhoids. In other respects, however, their condition differed but little from the general run of cases. (10) Those cases in which a systolic murmur at the apex of the heart was observed during the attack showed later an increase in the blood-pressure and in the size of the heart, as compared both with the mean of the observations made upon the same cases on admission to the hospital, and with the general average for the old typhoids.

Nearly one-quarter of those cases in which during the attack, systolic apical murmurs were detected, showed, on later examination, evidences of organic heart disease. Indeed, the majority of all the cases of organic cardiac lesions among the one hundred and eighty-three old typhoids came from this small group of thirty-one cases.

The infrequency of endocarditis as a complication after typhoid fever was a marked feature in Dr. Thayer's studies, only three of such cases having been observed in nearly one hundred necropsies at the Johns Hopkins Hospital.

The writer thinks that the influence of infectious diseases in general on the production of the more insidious endarteritic changes in the aorta and other vessels is a matter to which scarcely sufficient attention has been directed. "In brief," says Dr. Thayer, "there is much which goes to suggest that acute infections, and typhoid fever among them, play an important part in the etiology of arteriosclerosis. Some observers who have especially studied this question believe that after acute rheumatism, typhoid fever is the infectious disease most frequently resulting in changes in the heart and vessels. Dr. Thayer concludes a most instructive paper with the expression of the opinion that the result of his observations upon one hundred and eighty-three old typhoids will go to show that this disease is an active element in the etiology of a considerable number of cases of cardiac hypertrophy and dilatation, coming on sometimes early in life, as well as an important factor in the production of those vascular changes which Cazalis has happily called "*la rouille de la vie.*"

The deductions to be drawn from Dr. Thayer's paper certainly seem to favor the theory that the late effects of typhoid fever on the heart and vessels are very considerable, and there would seem to be grounds for the belief that with the exception of rheumatism, typhoid fever, of all the infectious maladies, exerts the most harmful influence upon the heart. The result of Dr. Thayer's further observations will be watched with much interest.

THE CONDITION OF THE UPPER AIR-PASSAGES BEFORE AND AFTER INTUBATION OF THE LARYNX.

DR. LOUIS FISCHER writes in the *Archives of Pediatrics* for February, on the above subject. A series of children that were operated upon several years ago were examined for the purpose of this study. The first series were patients at the Willard Parker Hospital, and the cases cover the years of 1896 to 1900. The children admitted to this hospital belong mainly to the laboring class of people. The cases dealt with by the author were ten in number, of which eight required one intubation, one three intubations and one four intubations. At the time that the writer examined these cases, one intubated seven years ago has had no illness since. Four intubated six years ago are in good health to-day. (One case remained entirely well, one had enlarged cervical lymph nodes, one had pneumonia one year later, one had pneumonia and paralysis and five years later had a second attack

of diphtheria but no laryngeal stenosis.) Five cases intubated three years ago are in good condition to-day. (Three had measles and bronchitis after recovery, one has not had a day's illness since intubation, one case had a mild attack of croup two years after intubation but did not require reintubation.) Rachitis seems to predispose to laryngeal stenosis, eight cases out of the ten reported in the series showed some form of rickets.

As to the condition of the throat, the writer observed that in all of the cases of this series some form of chronic tonsillar or pharyngeal condition was found. Adenoids were seen in two of the cases. Whether or no the hypertrophied tonsils seen in these cases were present at the time of intubation is not known. The fact that eight cases out of ten still showed enlarged tonsils, and one case, making nine cases, reported having had a tonsillotomy performed, proves that hypertrophied tonsils must have menaced the children's health before the intubation.

According to some authorities post-diphtheritic stenosis is a somewhat frequent sequel of intubation, but others state that they have seldom or never met this post-diphtheritic condition.

The second series of cases examined by Dr. Fischer were those intubated in private practice. Twenty-three cases were reported. The average length of time the tube was worn in the above twenty-three cases was 9½ days or 228 hours. Rachitis was very frequently encountered. None of the cases had a normal throat at the time of the intubation. Adenoid vegetations, enlarged tonsils, and chronic rhinopharyngitis were met with in almost every case. Absolutely normal conditions prevailed in the majority of sixteen cases. Laryngitis, lasting many months, was encountered in four cases.

Dr. Fischer disagrees with the late Dr. O'Dwyer as to the cause of postdiphtheritic stenosis of the larynx. The former maintained that the condition was the fault either of the operator or of the instruments. Dr. Fischer thinks that this view is proved to be wrong, at least in the average case, by the pathology of the condition. The writer is in accord with the opinions expressed by Dr. Emil Köhl at Zurich, in 1884, when he demonstrated most conclusively that not the least frequent cause of the difficulty is a chronic hypertrophic, subglottic laryngitis, a chronic thickening of the soft parts between the vocal cords and the lower border of the cricoid cartilage. Another and more frequent cause of stenosis was shown to be granulations and cicatrices in the neighborhood of the tracheal wound or cannula.

The conclusions arrived at by Dr. Fischer were as follows: "All the children in both these series that recovered had been breast-fed. This form of feeding must have had an important bearing on their bony development as well as their muscular structure. No chronic cough which could be attributed to the wearing of the tube was encountered. . . . Comparing an equal number of children who never suffered with diphtheria, nor were intubated, of the same age and development, it was found that they suffered with pneumonia and other infectious diseases in the same proportion as children in the writer's series of cases. This would seem to be a splendid argument in favor of intubation, as it shows two important points: First. The tolerance of the larynx to a tube for many weeks. Second. That a proper fitting tube constructed of rubber leaves no evidence of chronic inflammation directly traceable to the tube. . . . In spite of the fact that the large majority in the first series, as well as in the second, were decidedly rachitic, no deformity of the chest due to imperfect oxygenization could be attributed to the effects of the intubation tube. . . . It is safe to presume that chronic throat disease invites infection, and in the opinion of Dr. Fischer there is a direct relationship between the seed and the soil. If children's throats are in a normal condition, then the risk of infection is reduced to a minimum."

FURTHER REPORT ON SLEEPING SICKNESS IN UGANDA.

Lieut. Col. David Bruce, R.A.M.C., F.R.S., Dr. David Nabarro, and Captain E. D. W. Greig, I.M.S., were sent out to Uganda by the British Royal Society and the Indian Government, for the purpose of continuing the investigation of sleeping sickness, begun by Drs. Low, Castellani, and Christy in 1902. The report of the first named investigator has been published recently.

The report brings forward evidence to show (1) That sleeping sickness is caused by the entrance into the blood and cerebrospinal fluid of a species of trypanosoma. (2) That this species is probably that discovered by Forde and described by Dutton from the West Coast of Africa, and called by him Trypanosoma Gambiense. (3) That the so-called cases of trypanosoma fever, described from the West Coast, may be and probably are, cases of sleeping sickness in the earliest stages. (4) That monkeys are susceptible to sleeping sickness, and show the same symptoms, and run the same course, when the trypanosomes injected are derived from cases of so-called trypanosoma fever, or from the cerebrospinal fluid of cases of sleeping sickness. (5) That dogs and rats are partially susceptible, but that guinea-pigs, donkeys, oxen, goats, and sheep, up to the present, have shown themselves absolutely refractory. (6) That the trypanosomes are transmitted from the sick to the healthy by a species of tsetse-fly, Glossina palpalis, and by it alone. (7) That the distribution of sleeping sickness and Glossina palpalis correspond. (8) That sleeping sickness is, in short, a human tsetse-fly disease.

As is known, Dr. Castellani was the first to find trypanosomes in the cerebrospinal fluid of cases of sleeping sickness, due to his introduction of the method of centrifuging the cerebrospinal fluid in search for his streptococcus. This method at once put the latest investigators on the right track and led to the rapid and easy elucidation of this hitherto mysterious disease.

The following facts were discovered by the commission: (1) That cerebrospinal fluid of every case of sleeping sickness taken by lumbar puncture during life contains trypanosomes. (2) That trypanosomes occur in the cerebrospinal fluid of cases of sleeping sickness in other districts than Uganda. (3) That the cerebrospinal fluid taken by lumbar puncture from cases of disease other than sleeping sickness do not contain trypanosomes. (4) That

e peripheral blood of all cases of sleeping sickness so contains trypanosomes.

With regard to the connection between the -called trypanosoma fever and sleeping sickness e commission states that the symptoms of e two complaints are different. Trypanosoma ver appears to cause little or no inconvenience to ose harboring the parasite, whereas in sleeping kness the disease is a well-marked one and is variably fatal.

As to whether the blood of the general population, side and outside the sleeping-sickness area, contain ypanosomes, it was found from an examination of hty natives from the sleeping-sickness area that a rcentage of 28.7 had trypanosomes in their blood, hile those examined outside this area were not thus fected. The distribution of sleeping sickness was wn to coincide closely with the presence of the ossina palpalis.

The Glossina palpalis was found to be able to con- the trypanosoma from sleeping-sickness cases to althy animals. Five experiments to elucidate s point were made upon monkeys, with the result t the Glossina palpalis conveyed trypanosomes m sleeping-sickness cases to healthy monkeys up at least forty-eight hours after feeding.

On the whole, then the commission are justified in e statement that sleeping sickness is conveyed to man beings by the agency of the Uganda tsetse-. Perhaps further and more elaborate experi- nts will be needed ere this conclusion is generally cepted, but the evidence already available points rly to the Glossina palpalis as the conveyer of eping sickness to the human race in Uganda.

Blackwater Fever.

There are yet many diseases of which compara- ely little is known, and blackwater fever may classed among this number. Indeed, the aladies which prevail solely or mainly in tropical untries are only now beginning to be thoroughly vestigated. As the human race increases, and e lands of the temperate climes can no longer pport their vast multitudes, the tropics are ght to hold the surplus population. Thus as come about, that of late tropical diseases have n made the subject of careful study, for until far re knowledge of the means of prevention and ccessful treatment of these affections has been ned than is at present the case, those who make ir homes in the lands of the torrid zone, carry to a at extent their lives in their hands.

An editorial in the *Journal of the Royal British edical Corps*, for March, treats of blackwater ver, with reference to researches recently carried t by Messrs. Daniels, Christopher, and Stephens, which several interesting points regarding this adly complaint are mentioned. Attention is wn to the fact, as regards its geographical tribution, that where blackwater fever occurs alaria, and usually the so-called tropical variety, also endemic. The white race is peculiarly ceptible to the disease. Daniels defines the alady as "an acute hæmolysis of sudden onset, ort duration, and spontaneous cessation." He o thinks that the death rate has been overstated; om his own observations he puts it down at mewhat over 20 per cent. The three main uses are suppression of urine, cardiac failure, and yperpyrexia. The same writer, referring to treat- ent, states that in his opinion unless malarial parasites are found quinine should not be given. Sternberg's treatment for yellow fever (frequent doses of bicarbonate of soda and minute quantities of perchloride of mercury) seemed to yield good results.

As to the etiology of hæmoglobinuria, although the view is generally accepted that there is some connection between malaria and blackwater fever, the exact relationship has not yet been quite satisfactorily determined. Daniels points out that in British Central Africa, and in West Africa, similar anopheles are found, and these are not found in other countries. He suggests that possibly the different hosts may in some way modify the parasite.

Respecting the relation of the disease to quinine, Daniels notes that cases occur in which no quinine has been taken, that there is no relation between the time at which the quinine is taken and the onset of the disease, nor, between the quantity taken and the severity and duration of the attack.

Christoper and Stephens made some observations on the tonicity of the blood in blackwater fever and malaria. Their results showed that the blood in blackwater fever has a low tonicity, *i.e.* is resistant to hæmolysis, which they think may be explained by assuming that all the high tonicity corpuscles have already been destroyed. In malarial subjects there is usually a high tonicity. The blood of convalescents from blackwater fever resembles that of convalescents from malaria. The native's blood frequently showed a remarkably low tonicity. Hæmoglobinuric urine, and serum from a hæmoglobinuric patient had no hæmolytic action on the observer's blood. In vitro no difference could be detected between the patient's and the investigator's bloods as regards the solvent action of solution of quinine. The investigators suggest the possibility of the lethal action of quinine on the parasites setting free a large quantity of toxins and so causing the blackwater special parasite. Up to the present, however, no one has found any parasite special to the disease.

The views of Daniels, Christopher, and Stephens, respecting the connection between blackwater fever and quinine, conflict with those of Koch and some other observers. There is, however, ample reasons to believe that the conclusions arrived at by the British investigators are entitled to as much consideration as those of Professor Koch and his followers.

Diet in Diabetes.

Suitable diet is considered as important a factor in the treatment of diabetes as is the administration of drugs. The fact has been for some time recognized by the medical profession, that abstinence from all articles of food which may be converted into glucose, causes a marked decrease in the quantity of glucose in a diabetic patient's urine, and in every respect tends to an improvement in the condition of the majority of those afflicted with diabetes.

Sir James Sawyer of Birmingham in the *British Medical Journal*, March 5, points out that until the researches of Mossé two years ago, it was the therapeutic rule to withhold potatoes in saccharine diabetes. Mossé's researches led him to conclude that potatoes, far from being harmful, form a useful and beneficial food in glycosuria, and that they are capable of being substituted for ordinary wheaten bread in daily proportions sufficient to maintain the alimentary ratio—that is to say, in the proportion of two and one-half to three of potatoes for one of bread. Mossé found that a

daily ingestion of potatoes in quantities of from 1000 to 1500 grams caused, roughly, from 2 pounds to 3 pounds avoirdupois diminution of the glycosuria, quick relief of thirst, and general improvement in the patient. The reason for this beneficial action of potatoes in the feeding of diabetic persons is, according to Mossé, because the salts contained in potatoes are chiefly those of potash, and potash exerts a retarding influence on the progress of diabetes.

Sir James Sawyer states that his own experience in practice during the past two years is confirmatory of Mossé's conclusions, and he goes on to declare that in his opinion the beneficial results of Mossé's discovery and teaching as to the use of potatoes as a food in diabetes might well be carried much further in the dietetics of diabetics, than in merely the free allowance of properly cooked potatoes in a dietary. The writer proposes that the therapeutic difficulty as to the prohibition of ordinary bread for a diabetic may be met advantageously by making bread, cakes, and biscuits for diabetics by using the "flour" of properly cooked potatoes instead of the flour of grain. Sawyer's dietary for diabetics is as follows: May eat butcher's meat of all kinds, excepting liver, pork, ham, bacon, poultry, game, potatoes steamed in their "skins." Fish, oysters, crabs, lobsters animal soups, not thickened excepting by potatoes, mutton broth, beef-tea. Bran and potato bread or biscuits, potatoe cakes, eggs, cream, butter, cheese, greens, watercress, mustard and cress, lettuce, mushrooms, nuts, jelly or custard, unsweetened.

May not eat any bread or biscuts but those made of bran and potato, sugar, asparagus, broccoli, cauliflower, carrots, parsnips, French beans, peas, turnips, arrow root, macaroni, rice, sago, tapioca, vermicelli, pastry, excepting potato cakes, puddings, fruit, fresh and preserved.

May drink water tea, coffee, soda-water, claret, hock, spirits and water, unsweetened; bitter ale, very sparingly; milk, very sparingly.

May not drink cocoa, chocolate, champagne, porter, stout, home-made wines, liquors, cider, sweet wines and ale.

At one time the diabetic was greatly restricted in diet, but owing to the new views, promulgated first by Mossé, the sufferer from the disease has a wide choice of food and need no longer live a life of rigid self-denial. This more generous régime of living is to his physical advantage.

Bovine and Human Tuberculosis.

The February number of the *Maryland Medical Journal* is devoted to a consideration of tuberculosis viewed from several standpoints. The recent tuberculosis Exposition in Baltimore was the *raison d'être* of this issue, and provided the subject matter for the various articles contained therein. Whilst all the papers are written by well-known men, that by Ravenel, on bovine and animal tuberculosis, is, perhaps, under the present circumstances, the most interesting. Dr. Mazyck P. Ravenel has long been known as an opponent of Koch's theory that tuberculosis of man and tuberculosis of cattle are so different in their nature that it is impossible to transmit human tuberculosis to cattle. The writer approaches the subject from three standpoints—first, direct experimental transmission of tuberculosis from man to animals; second, clinical evidence of its transmission from animals to man; and third, theoretical considerations. The first point has been directly proved more than once, and thus may be briefly dismissed.

The second phase of the subject has never been experimentally proved directly, but accidental inoculation has taken place, some of which cases have ended in general infection, followed by death. Dr. Ravenel himself has had four such cases come under his observation, and in addition to these, quotes similar cases reported by Krause, Troje, Sprouk and Hofnagle, Lassar, Tschering, Pfeiffer, Kurt Maller, De Long, Joseph and Trautman.

The second consideration under this head is inoculation by ingestion. With regard to strict proof of this mode of infection very little evidence can be adduced, although there are many cases in which the evidence is very direct and very strong. Post-mortem evidence respecting infection by these means somewhat contradictory. In England a general average of primary intestinal tuberculosis is given of something over 25 per cent. Heller of Kiel, who while he found only 1.43 per cent. of primary intestinal tuberculosis, found but 37.8 per cent. in which the principal lesion was in the intestine, the mesenteric gland or the abdominal organs, "So that," says the writer, "we may conclude that all of these cases were of intestinal infection." Furthermore Professor Hueppe of Germany states that the percentage of primary intestinal tuberculosis in Germany varies from 25 to 30 per cent. The figures on this point in America indicate a much smaller percentage of primary intestinal infection. "Perhaps however," says Dr. Ravenel, "the strongest evidence we have of the infection of human beings by the bovine tubercle bacillus is the finding of bovine tubercle bacilli in the intestines of children who have died of intestinal tuberculosis."

The writer is of the opinion that the finding of the bovine tubercle bacillus in the intestinal tract of children, is by itself a proof that bovine tuberculosis is a factor in the spread of the disease in the human race, and he further believes that we are justified in saying that bovine tuberculosis is transmitted to the human race, chiefly to infants, in a certain proportion of instances, and is, therefore, a menace to human health.

Sunshine and Fresh Air vs. the Finsen Ultraviolet Rays and the Röntgen Rays in Tuberculosis of the Joints and Bones.

Dr. De Forest Willard read a paper with the title at the last meeting of the American Medical Association. The author argued that despite the fact of the Finsen ultraviolet rays and the Röntgen rays having undoubtedly an inhibiting effect on the progress of tuberculosis of the joints and bones, yet that the most powerful agents in our possession for the inhibition and destruction of the tubercle bacilli are sunlight and fresh air and abundant nourishment. Dr. Willard said: "The sun's rays are undoubtedly more helpful than any artificial rays, just as natural waters compounded by the chemistry of the Ruler of the universe differ very decidedly from the waters artificially compounded by the chemistry of man. While, experimentally, the strongest sunlight in summer takes more than an hour to kill bacteria, yet the ultimate influence is undoubtedly more beneficial than artificial contrivances." The author, after reviewing and discussing at some length the various methods of utilizing artificial light in the treatment of tuberculosis of the bones and joints, states the following as his conclusions: "(1) Sunlight, fresh air and good food, together with fixation and protection of the affected joint, are the most important agents in the contest with tuberculous infection. (2) Direct exposure to the rays of the sun is essential, and al

ospitals should be provided with solaria or sun orches and roof gardens. (3) Patients lying in ed should have the diseased joints exposed to the irect rays of the sun, their heads and eyes being rotected by green glasses or shades. The joints ay be covered with blue, so as to secure easiest assage of the ultraviolet actinic rays, and local edications rich in iodine may be also employed if esired. (4) Tent life on the hospital grounds, or etter, in the open pine forest, can be successfully nployed through both summer and winter. (5) natoria should be established for tuberculosis of he hard tissues, as well as of the soft. (6) The ncentration of the sun's rays by lenses, as sug-sted by Butler, Finsen and others, is of positive nefit in bactericidal influence. As final curative ents, however, the direct sun's rays are most ective. Electrical rays can be used when sun-ht is lacking. (7) The Röntgen rays in the boratory have an inhibitory power on the tubercle cilli, and may prove useful in restraining the owth of these microorganisms in living tissues.

The actinic rays and the *x*-rays are both apparently helpful in the fight with tuberculosis, but eral years will be required to determine accurately ir effect. They should be employed not to ersede, but to antedate and to supplement rative procedures, to assist the mechanical tection of the joint, and to increase the general rapeutic measures employed."

Dr. Willard's views are certainly based on sound mmon sense. For any form of tuberculosis, sun-t, fresh air, and good living are by far the most ctive curative remedies known. Other forms of atment may aid in restoring the consumptive to lth, but the main factors in bringing about this ult must always be nature's own work.

Professional Prevarication.

The *Columbus Medical Journal*, February, con-ns a paper on the above subject, which was deliv-d in the form of a toast by Dr. Harry A. March Canton, Ohio, at the banquet of the Canton dical Society on January 8. The writer declaims inst the old-established custom of medical men telling the truth, the whole truth, and nothing t the truth, concerning their patients.

Professional prevarication, he thinks, is very ch in evidence when physicians are in the position expert witnesses—they lean, albeit, it may be, ost unconsciously to the side on which they are ined.

The most universal custom is, however, that of ing a patient that he or she is much more ill than ally the case. Still more reprehensible, thinks March, is the custom of teaching every girl ering womanhood that she is suffering with rine or ovarian trouble, thus guiding her into the nues of hysteria and neurasthenia.

The writer also falls foul of the deceit frequently ctised, of hiding from a patient for any length of e, his real condition. Dr. March believes it to be physician's duty—his absolute duty—to tell truth to the patient, that climate and diet all needful aids may be secured to save from his fate and from his friends, for his tection and for the safety of his dear ones. ain, if a patient be on his deathbed and hope-always, the writer deems it to be the phy-ian's duty to inform him of his true condition, bluntly and cruelly, but tactfully and sym-thetically. The paper ends with these words: The time is past, if indeed, such time ever existed, when a great body of scientific men must descend to petty subterfuge to retain patients and secure dollars. Professional prevarication, like the manacles and chains of the madhouse, is a relic of unscientific and unprofessional barbarism, and tactful truth, the therapeutic agent, the prophylactic agent, for the regeneration of diseased humanity, for the saving of countless lives and the avoidance of indescribable misery."

It may be that Dr. March is right and that the doctor sometimes withholds the truth when it would be more honest and better for the patient to know the real facts of the case. On the other hand, much must be left to the physician's discretion as to what he shall say and what he shall not. As a general rule, however, the physician is always warranted in giving every hopeful view possible to his patient even under most threatening conditions. To the friends of the sick one he is always privileged to give, on the other hand, a necessarily guarded prognosis.

News of the Week.

Union of the State Medical Societies.—Action having been taken for consolidation of the medical profession of the State by both the State bodies, the committee deems it advisable to take the necessary legal steps before the Supreme Court in May. Before doing this it is important that every county society shall take action upon the ratification resolutions, but less than half of the societies have acted. A circular has therefore been sent to each county society urging the members to secure a special meeting of the society during April, and to act in this matter, using the form of resolutions which has been sent to each secretary. All are interested in having no obstacle in the way of perfecting this unification, and it is hoped that speedy ratification will be effected by all the county organizations.

Pathological Exhibit at the St. Louis World's Fair.—There will be a pathological exhibit at the World's Fair in St. Louis under the auspices of the American Medical Association. The exhibit, which will be held in the Palace of Education in a gallery over the East main entrance, will be of wide scope, covering the field of general pathology and bacteriology. The president of the association has appointed the following Exhibit Committee to take charge of the work: *Executive Members:* Ludwig Hektoen, Chicago; A. J. Ochsner, Chicago; W. A. Evans, Chicago; W. T. Eckley, Chicago; L. F. Barker, Chicago. *District Members:* J. N. Hurty, World's Fair; Frank P. Wynn, Indianapolis; Max Herzog, Philippine Islands; V. C. Vaughan, Ann Arbor; W. W. Keen, Philadelphia; J. S. Billings, Jr., New York; Philip King Brown, San Francisco; Ellsworth Smith, Jr., St. Louis; Allan J. Smith, Philadelphia; F. W. Farham, New Orleans; R. M. O'Reilly, U. S. Surgeon-General. Dr. Ellsworth Smith, Jr., who has charge of the St. Louis district, has appointed the following Advisory Committee to assist him in the organization of an exhibit for his district: Y. H. Bond, H. W. Bond, John Young Brown, B. Meade Bolton, Willard Bartlett, N. B. Carson, O. H. Elbrecht, W. E. Fischel, B. M. Hypes, Bransford Lewis, H. W. Loeb, Robert Leudeking, H. G. Mudd, Henry Schwarz, Chas. Shattinger, J. H. Simon, C. A. Snodgrass, Justin Steer, Hugo Summa, Robert Terry, E. F. Tiedemann, and H. Tuholske.

Organized Dental and Medical Professions.—The Chicago Medical Society and the organized dental profession agree that all questions of legislation and larger public policy relating to medical

and dental affairs shall be referred to a committee, to be known as the Committee on Public Relations. This committee is to consist of ten members, five from each profession. It shall have a chairman and a secretary. Any question of public policy or public relation affecting either the medical or dental profession, or of legislation affecting, directly or indirectly, either of them, can be referred to this committee. It will be the duty of the committee carefully to consider these questions. It will have the power to recommend either specific action or general attitude to the societies from which the members come as delegates. There shall be an annual meeting of the committee, at which organization shall be effected and continued. Other than this, the meetings shall be special, and can be called by the president or by any two members. The officers shall be elected for one year. The method of election of the delegates and the length of their service shall be regulated by the societies which they represent.

Loving Cups for Dr. Lefferts.—Prof. George M. Lefferts, who recently resigned the professorship of laryngology in the College of Physicians and Surgeons, delivered his farewell lecture on Monday, March 28. Both his clinical assistants and the fourth-year class took this opportunity to present him with silver loving cups. The handsome cup of the class of 1904 was first presented, the orator being the class president, Mr. G. H. Lathrope. Immediately following occurred the presentation of an artistic cup from the staff of clinical assistants; the incoming professor, William K. Simpson, M.D., making the address. Dr. Lefferts, in reply, referred pleasantly to the fact that, more lucky than Sir Thomas Lipton, he had that day "lifted" two cups. He gave a short history of the clinic, from its foundation in 1875 to the present time. The valuable museum of teaching apparatus he had deeded to the trustees of Columbia, for the free use of the coming generations of medical students. Finally, he said a few words of farewell, first to his assistants and then to the students.

United States Association for the Study of Tuberculosis.—At a well-attended convention, held on March 28 in the hall of the College of Physicians of Philadelphia, under the chairmanship of Dr. Wm. Osler of Baltimore, a resolution was adopted that a committee of five be appointed to effect the organization of the United States Association for the Study of Tuberculosis, and Drs. E. L. Trudeau, George M. Sternberg, W. H. Welch, L. F. Flick, and H. M. Biggs were appointed members of the committee. Dr. Wm. Osler was chosen chairman and Dr. H. Barton Jacobs, secretary for the committee, when it shall meet in connection with the American Medical Association at the annual session in June at Atlantic City. In the absence of Prof. Eduardo Maragliano of Genoa, his paper on the "Specific Therapy of Tuberculosis, and Vaccination against the Disease," was read for him. As a result of clinical and laboratory observations covering a period of thirty-four years, the conclusion was expressed that it is possible to employ a specific therapy against tuberculosis and also to immunize the animal organism against the same disease, and finally that there is good reason to hope for an anti-tuberculous vaccintion for man. The anniversary dinner of The Henry Phipps Institute was given by the staff at the University Club on the evening of the same day. The delegates to the convention were all invited guests of the occasion. Sixty-two persons were present. The feature of the evening was the presentation of a silver pitcher to Dr. Lawrence F. Flick, the Director of the Henry Phipps Institute, by the members of the staff, as a token of their esteem. Mr. Henry Phipp the founder of the institute, made the presentati in the name of the staff.

The Crowded Hospitals.—A census of hospit inmates was made by *Charities* on March 19, a the result showed that the number of availal beds to meet the needs of some disaster, furnishi suddenly a large number of wounded, was smal even than it was eight weeks ago in the middle the winter. In six of the city hospitals, having capacity of 2,590 beds, there were 3,043 patients, 453 more than there were beds for. In fourte private hospitals with a combined capacity 2,856 beds, there were 2,347 patients, leaving vacant beds. Combining these figures we f that in the twenty largest general hospitals in city, having a capacity of 5,446 beds, there w 5,390 patients on March 19, leaving in New Y City but 56 vacant beds. But these statistics of course, misleading, for there were really vacant beds, the 453 bedless patients in the hospitals being put on mattresses on the floor not occupying the vacant beds in the priv hospitals.

New Hospitals for the Insane.—Nearly a mil and a half dollars is now being spent, or is ab to be spent, in some nine different States for buildings for the insane. This is exclusive New York State, where between $600,000 $900,000 is annually expended for this purp It would seem pertinent to inquire whether t might not be an increase in efficiency and decr in cost if the experience of the different St were in some way made available to one anot There is practically the same class of patients t provided for in all cases, and there is little re why buildings which have been found suitabl Massachusetts should not be suitable in Ore The building operations now under way, or ready planned, include entirely new institution Norwich, Conn.; Allentown, Pa.; and Parsons, K and additions to existing buildings at Morrist and Harrisburg, Pa.; Spring Grove and Sykesb Md.; Dunning and Watertown, Ill.; Lyons V Tenn.; Hopkinsville, Ky.; San Jose, Cal.; El Mich.; Las Vegas, New Mexico; Norfolk, Neb., Pineville, La.—*Charities.*

Radium in Blindness.—A recent cable dispat *The Sun* states that Professor Greef, chief of eye clinic at the Berlin University, has stu at the wish of Emperor William, a St. Peters report that blind persons in some cases are abl see objects illuminated by radium rays. Profe Greef found that those whose optic nerve had been destroyed could distinguish objects in f of a screen made fluorescent by radium, but he found that they could distinguish objects on a s transparent screen illuminated by an ordinary l He concluded that the blind cannot hope for slightest help from radium.

Pathological Bulletins of the University of fornia.—Announcement has been made of the tial numbers of a series of Bulletins on Patho from the laboratory of the Medical Departme the University of California, Berkley, under editorship of Dr. Alonzo E. Taylor, head of department of pathology, and director of the He Laboratory in San Francisco. Original wor reported in the quantitative separation of gl lins of hæmolytic serum, with especial referen the carbon dioxide group, and other subjects.

The Red Cross Society.—It is reported fr Washington that several members of the Co gressional Committee appointed to investigate t

American National Red Cross Society are strongly of the opinion that there should be a new organization having absolutely no connection with the present body and that the new Red Cross should receive the sanction of the Government and be under Government supervision. If the committee adopts this recommendation, a resolution will probably be introduced in Congress, authorizing the President to appoint a commission to prepare a scheme of organization for a new society.

Civil-service Examinations will be held on April 9 for the following positions among others: Apothecary in State hospitals and institutions, assistant in entomology in the State Museum, health officer for the town of Coventry, and physicians in State hospitals and institutions of both regular and homœopathic schools, stenographer in State hospitals and institutions. Applications for these examinations must be made on or before April 14. Full particulars of the examinations and blank applications may be obtained by addressing the Chief Examiner of the State Civil Service Commission at Albany.

Dr. Daniel H. Craig.—At its meeting on March 1, 1904, the Massachusetts Medical Society, Suffolk District, Section for Obstetrics and Diseases of Women, elected Dr. Daniel H. Craig as its president. On March 24, 1904, after presenting a paper for their consideration, Dr. Daniel H. Craig was given an honorary membership in the New Hampshire Surgical Club, at its semi-annual session, held at Concord, N. H.

Dr. Jacob E. Schadle of St. Paul, Minn., has been appointed professor of rhinology and laryngology in the College of Medicine and Surgery of the University of Minnesota, Minn., to succeed Dr. Laton, resigned.

East End Hospital.—Councilman Kellogg of Cincinnati has introduced an ordinance to condemn a twenty-five foot lot on Eastern Avenue for the purpose of building an East End Emergency Hospital. This lot is in a railroad and factory district, and is three miles from the nearest hospital.

Gift to Jewish Hospital.—The sum of $5,000 will be given to the New Children's Department of the Jewish Hospital, Cincinnati, by Mr. A. J. Seasongood, and Dr. Sigmond Stark, trustees under the will of Miss Laura Seasongood. One thousand dollars will also be given to the Jewish Home for Incurables. Four thousand dollars has been expended for land adjoining the present hospital site on Burnet Avenue, and this will be used for the erection of new buildings.

The Death Rate in Cincinnati has markedly decreased in the past week, only thirty-two deaths from contagious and infectious diseases were reported to the Health Department last week, twenty-one being from consumption and six from typhoid fever. Measles is rapidly disappearing, only fifty-eight new cases and but one death being reported.

Hospital Fire.—The Delta County Hospital located at Escanaba, Mich., took fire on March 25, and sixty patients were forced to leave the building, many with only scanty clothing. The fire was controlled within an hour.

The Panama Canal Commission, which sailed from New York on March 29, took as sanitary officers Drs. William C. Gorgas and Louis La Garde of the United States Army and Dr. Ross of the Navy.

The Loomis Laboratory.—The Court of Appeals has recently affirmed the judgment of the lower courts in deciding that New York University has no right or title to the lands or properties of the Loomis laboratory at 414 East Twenty-sixth street. The laboratory was founded out of a $100,000 fund contributed by Dr. Alfred L. Loomis in 1887. Its properties are now valued at $200,000.

New Fire Department Surgeons.—Commissioner Hayes of the Fire Department of New York City has announced the appointment as surgeon of the department of Dr. Linnæus J. Hunter for the Boroughs of Manhattan and the Bronx, and Dr. James A. Kennedy for the Boroughs of Brooklyn and Queens. The salary is $2,000 per annum.

Plague in Peru.—United States Minister Dudley cabled the State Department from Lima last week that bubonic plague had broken out in San Pedro, Callao, and Lima.

A Legal Decision on the Pathogenesis of Cancer. Dr. Fred Bangs of San José, Cal., has been sued for $25,000 on the allegation that his treatment of an injured female breast produced a cancerous growth. The question of pathogenesis involved throws a heavy burden on the prosecution.

Guarding Against Trichinosis in Hogs.—The Board of Health of Los Angeles is to be commended for its decision asking that all pork "from hogs fed on the viscera of cattle, sheep, and hogs" be condemned.

Coroner's Red Tape.—Dr. August F. Reinhold of San Francisco died on March 3 of pneumonia. One of the provisions in his will led to some embarrassment. His body was left to science, but as the coroner had ordered an autopsy, none of the colleges desired to accept it. The reason given by the coroner for the necessity of a post-mortem examination was that the last attending physician had not registered.

The Indian Territory Medical Association.—The next annual meeting of this society will be held at Holdenville, I. T., on June 7, 8, and 9. The officers of the association are: *President*, Dr. W. A. Tolleson of Eufaula; *Vice-Presidents*, Drs. David Gardner of Lehigh, and J. W. Gilbert of Roff; *Secretary* and *Treasurer*, Dr. R. J. Crabill of South McAlester.

The Western District (I. T.) Medical Association.—The next semi-annual meeting of this society will be held at Okmulgee, I. T., on April 12 and 13, under the presidency of Dr. W. M. Catt. The secretary and treasurer is Dr. Claude A. Thompson.

The Gastroenterological Association.—The seventh annual meeting of this association will be held at Haddon Hall, Atlantic City, N. J., on June 6 and 7. The sessions will be devoted mainly to a set discussion on gastric ulcer, to be opened by Dr. J. C. Hemmeter of Baltimore. The annual dinner is announced for the first day of the session at 7:30 P.M.

The American Association of Pathologists and Bacteriologists was announced to hold its fourth annual meeting in this city on Friday and Saturday of this week, under the presidency of Dr. Eugene Hodenpyl. Professor Ehrlich was expected to address the society on Friday afternoon.

An Anti-cocaine Law.—The Virginia Legislature has recently passed a law which goes into effect within sixty days, forbidding the sale of cocaine, and no one can buy it except physicians, dentists, and druggists. The present law on the subject is not so stringent. It is said that cocaine addiction is a common vice among the street Arabs of Richmond, and is encouraged by some conscienceless druggists who sell the drug in any quantity to the boys and others without ascertaining the use to which it is put. It is hoped the penalties for violation of this new law will put a stop to this practice.

The Late Dr. Fridenberg.—At the March meeting of the New York Otological Society, the undersigned having been appointed to draft resolutions on the death of Dr. Edward Fridenberg, reported as follows:

Whereas, The death of Dr. Edward Fridenberg has removed one of its original and most earnest members, whose ability and energy had won for him an eminent and honorable position among the members of the medical profession, whose broad education had earned the esteem of his colleagues, and whose kindness and devotion to duty had endeared him to many friends and patients.

Therefore be it resolved, That the New York Otological Society place upon its minutes this expression of loss; that it extend its sympathy to his family in this great sorrow; and that a copy of these resolutions be sent to them and be published in the medical press of this city.

(Signed) CHARLES H. MAY, M.D.,
JOHN L. ADAMS, M.D.

Obituary Notes.—Dr. WILLIAM ALFRED MCCORN died on February 18 of mastoiditis. He was born in Newfield, N. Y., forty-five years ago and was graduated in arts from Cornell, and in medicine from the Medical Department of the University of Buffalo. He was an alienist and had at various times been connected with New York State hospitals for the insane, and with the Kankakee, Ill., Hospital. He left a widow and one daughter.

Dr. JOHN METCALF POLK, the son of Dr. William M. Polk, died of pneumonia at the home of his parents, in this city, on March 29. He was born May 6, 1875, and was graduated from the Sheffield Scientific School of Yale University, receiving the degree of Ph.B. in 1896, and from the Cornell University Medical College in 1899. He served a term as interne in Bellevue Hospital and then took a post-graduate course abroad, chiefly in Vienna. He was instructor in medicine and in physical diagnosis in the Cornell Medical College and was adjunct-assistant physician in Bellevue Hospital.

Dr. DAVID MACKAY, seventy-one years old, died on March 23 at Dallas, Texas. He was born in Glasgow and served on an English warship in the Crimean War as surgeon. In the Civil War he was under Burnside in the Army of the Potomac. Later he was city physician at New Orleans. He was a member of the Board of Pension Examiners, and for six years was surgeon-general of the Grand Army of the Republic of the United States. He was a man of deep research, and noted for wide philanthropy.

Dr. HARRY S. DISSLER of Schoeneck, Lancaster County, Pa., died of acute nephritis in Philadelphia in the Medico-Chirurgical Hospital on March 19, at the age of twenty-two years. He was graduated from the Medico-Chirurgical College in the class of 1903.

Dr. LAWRENCE L. GLOVER died at Haddonfield, N. J., on March 21 at the age of thirty-seven years. He was an assistant surgeon in the Naval Reserve.

Dr. THAD L. JOHNSON died on March 5 at Pomona, Cal., after a lingering illness, at the age of thirty-eight. His father is a practising physician at Riverside.

Dr. ROBERT S. MURPHY of Dublin, Ireland, died on March 5 at Mentone, Cal., in his sixty-fourth year. He came to California six months ago on account of tuberculosis.

Dr. HANS H. BEHR, a native of Koethen, Germany, died at San Francisco, on March 6, at the age of eighty-five. He was a professor in the California College of Pharmacy.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE KING'S HOSPITAL FUND—PARLIAMENTARY—MRS GARRETT-ANDERSON—PREVENTION OF CONSUMPTION—INFLUENCE OF ADRENALIN ON METABOLISM—HÆMATOPORPHYRINURIA—WEST-INDIAN DISEASES—HOME OF RECOVERY—WHAT IS A QUACK IN LAW?—HOSPITAL MEETINGS—SIR T. FRASER—SIR S. WILKS—DEATH OF DR. DAVIDSON.

LONDON, March 11, 1904.

THE council of the King's Hospital Fund held its annual meeting on Tuesday, the Prince of Wales, as president, in the chair. The annual subscriptions had increased during the year by £4,000, while the League of Mercy had contributed £2,000 more than in any previous year. The council had resolved to distribute £100,000, which involves drawing on reserves for £18,751; but the money being at the discretion of the council, this action was felt to be justified, having regard to present needs and in full reliance on the continued sympathy and support of the public. Every hospital to which a grant was made was inspected and reported on. The working expenses were less than 2¾ per cent. The fund has now an invested capital of £664,000,255.

The Prince, in moving the adoption of the report, read a letter from one of his personal friends, who wishes to remain anonymous, in which His Royal Highness was offered for the fund by way of gift securities representing £4,600 a year, on condition that £9,332 per annum be provided for by December next. The letter stated that the writer thought that the King's Fund should, as soon as possible, be able to distribute £150,000 a year, and to enable it so to do he proposed to anticipate a provision in his will for the purpose. The writer added that he attached no other condition, but he expressed a hope that no part of the fund subscribed for the relief of the sick poor should be diverted to purposes of medical education. The Prince also delivered a message from the King to the effect that His Majesty's interest in the fund continues unabated.

Yesterday the Prince had another pleasant surprise—a cheque for £250 from the Sunday Concert Society in commemoration of their two hundredth concert. The occasion was determined to be celebrated by a grant from the society's surplus funds "to some charitable purpose of unquestioned public usefulness." The cheque was handed to the Prince of Wales with a request that he would allocate it to such fund or funds as he might decide. As president of the King's Fund, the Prince naturally handed it to that.

The King has quite recovered from the rather severe cold he took at the Cambridge celebration, and which prevented him from going to St. Paul's on Sunday, with the Queen, to celebrate the centenary of the Bible Society.

In the House of Commons the medical members have formed themselves into a committee which will watch over the progress of medical and sanitary proposals much as the Service Committee does over affairs concerning the army and navy. Sir M. Foster will act as honorary secretary of this medical committee, and M.P.'s who are interested in sanitary affairs but are not doctors will be asked to coöperate.

Dr. Farquharson, on Tuesday, in the discussion on the army estimates, congratulated the government on the satisfaction of the medical department, for which Mr. Broderick was to be thanked rather than his successor. But he went on to give a serious warning against wasteful and cheeseparing such as had at times prevailed, and more serious still against the withdrawal of concessions which had at times taken place and always created suspicion and discontent. He further referred with regret to the omission of the medical director-general from the new Army Council—a really dangerous experiment.

Mrs. Garrett-Anderson, honorary secretary of the Imperial Vaccination League, is getting up a manifesto in favor of the revaccination bill introduced to the House of Commons by Sir J. Batty Tuke. The bill provides for revaccination between twelve and thirteen years of age and is down for consideration on April 26, but it is not likely to come on.

Mrs. Anderson is about to retire from the staff of the new hospital for women which she was instrumental in founding thirty-two years ago, and of which the annual meeting was held on Tuesday. The report stated that 612 in patients and 7,629 out had been treated during the year, 387 cases being surgical and 18 ophthalmic. Sir Wm. Broadbent paid a tribute to the work of Mrs. Garrett-Anderson, and accentuated the value of women as doctors. Dr. Cullingworth also spoke.

Yesterday the fifth annual meeting of the National

Association for the Prevention of Consumption was held, the Earl of Derby presiding. His Lordship had evidently been well coached, and made an excellent speech reviewing the year's work. Progress in promoting sanatoria was reported. There are now about seventy in the United Kingdom with 2,760 beds, but most of them are for paying patients. When the King's sanatorium is completed it will add another hundred beds. It has often been proposed to utilize in some way the vacant hospitals erected for smallpox in a panic by the extravagant Asylums Board and sanctioned by the Local Government Board. There are 1,850 beds in these derelict buildings, and it is very unlikely that they will be wanted for smallpox. Why should they remain untenanted? The association would like to have them utilized for tuberculosis, and certainly either this or some other use should be made of them. From the report it seems that the Central Association now has 935 members, and there are twenty branches, bringing the total number up to 2,900. The branches have full control of their own affairs, are in fact independent societies.

Sir Wm. Church, speaking to the report, referred to the unreasonable dread that some persons have of the infectiousness of tuberculosis, especially in the more educated class and those who read the sensational papers. They fancied all they could do was to get at a distance from the bacillus, and so neglected the hygienic measures which would put them in a state to resist the invasion of the microbe. He also advocated the erection of inexpensive buildings for sanatoria instead of expending vast sums on bricks and mortar. The association might very well be invited by local bodies to act as their advisers.

Mr. Malcolm Morris said the association was passing through a financial crisis. Without more money the good work must come to an end. He had sent out 5,000 circulars, but the response to his appeal did not exceed £100.

The Royal Commission on Tuberculosis has been misrepresented in the press as having nearly completed its work. A question in parliament has corrected the statement. The experiments are going on, and it is quite impossible to say when the investigation will be reported on.

At the Pathological Society's meeting last week, Dr. Noel Paton gave an account of a research in which he is engaged on the influence of adrenalin on the nitrogenous metabolism of birds. His object is to settle whether adrenalin produces glycosuria in birds as it does in mammals. It has previously been shown that removal of the pancreas from ducks and pigeons is followed by diabetes, so that this organ cannot play the part it does in dogs in regulating the metabolism of sugar. Dr. Paton has been experimenting on geese, and finds that large doses of adrenalin by subcutaneous injection cause glycosuria as in mammals. Moreover, it produced a marked decrease in the uric acid nitrogen and other bodies precipitated by phosphowolframic acid. Of these about 90 per cent. is uric acid. Further, he finds a distinct decrease in the proportion of ammonia nitrogen, and in one experiment a decrease in the urea nitrogen. It would, therefore, seem that adrenalin interferes with the elaboration in the liver of the end products—uric acid in one case, urea in the other.

At the same meeting Dr. A. E. Garrod reviewed the recorded cases of hæmatoporphyrinuria in which sulphonal had never been taken. The evidence was opposed to the view that excessive hæmolysis was a cause, and pointed rather to perverted hæmoglobin catabolism. Although the slight excess of hæmatoporphyrin often excreted in disease seems to point to diffuse changes in the liver, it cannot at present be stated that the profound disturbance of pigment metabolism which gives rise to the hæmatoporphyrinuria with dark red urine is wholly due to liver disease. Still, serious degenerative changes in the liver have been seen in some fatal cases which seem to have been caused by sulphonal.

Sir Patrick Manson read a paper on Tuesday before the West India committee on "The Disease Problem in the West Indies." Among the diseases prevailing there he mentioned malaria, tuberculosis, dysentery, filariasis, etc. In fact he said all the tropical diseases were there met with. He showed by lantern illustrations the instrumentalities of mosquitoes, flies and other insects, and held that if the knowledge already accumulated can be applied, many of the maladies can be controlled, if not abolished. Tuberculosis will be checked when the negroes have been induced to improve their houses and keep the doors and windows open; malaria, filariasis and yellow fever when people use mosquito nets and suppress puddles; dysentery and anæmia when proper conservancy has been instituted and pure water supplied; excessive infant mortality when negro mothers have been taught how to feed their babies. All these things he held to be within the power of an intelligent sanitation, and he suggested that a well-equipped laboratory should be established in the West Indies, and every boy and girl in the colonial schools taught the leading facts of a rational system of tropical sanitation.

What is a quack? The Lord Chief Justice, in summing up a libel case that has occupied the court most of the week, said it meant "a boastful pretender to medical skill which he does not possess." Certainly that is one sort of quack, but there are others, and I doubt if the word can be restricted to such a definition. His Lordship told the jury it had been for many years decided that to call a medical man a quack is libelous.

The case arose out of a paragraph in *Truth* to the effect that one H. N. Dakhyl, who appends to his name M.D., Paris, and calls himself a specialist for deafness, etc., but of course is not a qualified medical man, happens to be late physician to the notorious Drouet institution—"in other words a quack of the rankest species." It is further presumed by the writer of the paragraph "that he left the Drouet gang in order to carry on a practice of the same class on his own account, and probably he is well qualified to succeed in that particular line." On this a suit for libel was brought against Mr. Labouchere, M.P., the proprietor of *Truth*. The judge told the jury plaintiff was qualified as far as M.D., Paris, goes, "that is to say he was a skilled man." He was also a man that the law allowed to practise here though he was not registered under the medical acts. The subject of foreign medical men practising here did not concern the jury. They must not mix up comment on a matter of public interest with a personal libel. Defendant was properly entitled to comment on such matters, but if in doing so he libeled private individuals he had no protection. The system carried on by the Drouet institution and afterward by plaintiff himself was distinct from his character or competence. Though the jury might think it ungentlemanly and unprofessional to advertise, it was not against the law and "one might have sympathy with a man who was struggling." Defendant was "not entitled to call him a quack because he advertised." The judge had further been struck by some of the evidence as to the danger of treatment by correspondence, "but if it could not be shown that he had done harm, that to a certain extent was an answer." It was for the jury to consider whether the plaintiff was carrying on a practice which no medical man ought to be allowed to conduct. They considered it "to a certain extent," that is about half an hour, and gave the plaintiff damages at £1,000. No doubt there will be an appeal. The whole case illustrates the bungle of our law, which pretends to regulate the profession, but affords it no real protection. The Medical Council has never taken up a proper position but been content to squabble over vested interests until, as happened in this case, it can be shown that, though a man is struck off the Register for the Drouet system, another can follow it with impunity.

A "Home of Recovery" is to be added to London's charitable institutions. The object is to provide a home and surgical care for patients discharged from the hospitals after operations and who need a further period of rest before they are able to resume their occupations. With rare exceptions the convalescent homes hardly meet these cases, and it is proposed to build and endow a home for the purpose. The Earl and Countess of Lytton held a drawing-room meeting in aid of the scheme on Monday, when a distinguished company determined to carry out the plan. Mr. Asquith said the doctors were absolutely unanimous in favor of the scheme and made a feeble joke about "their infinite capacity for honest divergence of opinion on every conceivable problem." What of the lawyer's capacity for divergence, honest or not, provided it be paid for?

Dr. Herbert Snow has sent a letter to the newspapers deprecating a misapprehension of his recent address at the Cancer Hospital. He disclaims being pessimistic, but holds the best schemes of research must fail in the absence of a careful classification of the numerous diseases vaguely called cancer. It is not surprising that reporters should not exactly appreciate the points of an address on such a subject to the subscribers of the hospital.

The thirty-first anniversary of the Medical Society was celebrated on Tuesday evening after the usual manner by a dinner, Dr. deHaviland Hall, president, in the chair, and the fellows present, with the guests, numbering 205.

The City of London Hospital for Diseases of the Chest had its annual meeting yesterday. The income was £10,000 but the expenses were £12,000, and a loan from the bankers had been contracted *pro tem.* Still the committee had recommended the erection of a home for the nurses at a cost of over £3,000. The public it is hoped will come to the rescue of this excellent hospital.

The annual meeting of the Royal Dental was also held yesterday. Money is urgently needed for this institution, which is the great school of dentistry in the Kingdom.

The Ecclesiastical Commissioners own large estates in proximity to the new site for King's College Hospital. They have therefore subscribed £2,500 to the Removal

Fund, as their poorer tenants will naturally benefit from the hospital being so near them.

The King has intimated that he hopes to lay the foundation stone of St. Bartholomew's new building in June or July. The fund for this hospital has passed £50,000.

The King has appointed Sir Thos. Fraser to be one of his honorary physicians in Scotland.

I regret to say that Sir Samuel Wilks has not made good progress during the week.

The death is announced of Dr. Alexander Davidson, consulting physician to the Royal Infirmary, in the rebuilding of which he much assisted. In fact with Sir Mitchell Banks, his colleague, he was quite a leader in that effort as well as in the establishment of University College, Liverpool, now Victoria University, in which he was for some time Professor of Pathology. He graduated at Edinburgh, M.A., M.B., 1863, and M.D., 1874. In the last named year he became a member of the London College of Physicians and was elected Fellow in 1885. He was formerly on the staff of the Northern Hospital and of the Infirmary for Children. He was much interested in nervous diseases, and among his contributions to the subject I may name "Nerve-stretching in Locomotor Ataxia," "Vertigo," and the "Cerebral Manifestations of Lead Poisoning" in the *Liverpool Medico-Chirurgical Journal*, 1881–96; "Syphilitic Disease of the Cerebral Arteries," in the Pathological Transactions, 1877; also various articles in "Quain's Dictionary."

PHYSICIANS PREVENTED USING THE LIBRARY OF THE ACADEMY OF MEDICINE.

To the Editor of the Medical Record:

Sir: Some weeks ago a New York medical weekly published the complaint of an anonymous writer who felt uneasy about the present and future condition of the New York Academy of Medicine because it managed its own affairs. The academy was told that such financial support as it had obtained was afforded because donors expected to contribute for the general medical public; and that those who contemplated giving to the library would hesitate in future. These anonymous suggestions to which nobody cared to reply on account of their being anonymous (I do not care to use a synonym) are also contained in the strikingly similar language of a letter published by Dr. Sam'l G. Tracy in the Medical Record (p. 507). Both (?) writers will be pleased however when they may learn—what can easily be proven—not only that the library of the academy is mainly supported by the dues of the fellows, but also that contributors (not members of the academy) gave their money without any restrictions, merely through their knowledge of the history and the usefulness of the academy.

Dr. Sam'l G. Tracy is not a fellow of the academy; not a member of the Medical Society of the County of New York; not a member of the New York County Medical Association. It is these negative qualities which may enable him to criticise public medical affairs—in his own opinion—in as much as he is so far above and outside them—indeed he may take a bird's eye view of them—but he will admit that the Academy may have something to say for itself, and may have rights of its own.

Academicians have complained for years they could not find access to their own library because every available space was taken up by non-members. The latter class were found to amount to more than 60 per cent. of the readers.

Books were taken home by non-members that were wanted by fellows.

Men in ample circumstances and "in good standing" when requested to join the academy and, like good citizens, aid in the support of the splendid institution would smile or grin. Not they, oh no. They would not think of paying for what the academy gave them and everybody gratis.

We have on file the resignation of a former fellow who told the academy bluntly that he did not mean to pay any longer for what the academy gave away gratis, just as we have on file the sneering letter of another gentleman who resigned because the academy refused to pay him six dollars which nobody owed him.

For many years the academy has been generous to the medical and lay public. It has for the small amount of twenty dollars annually furnished almost unlimited facilities to its members and those who could not or would not contribute to its support. It has built up the second best medical library of the country (one of the best in the world). It has kept it open for everybody until its own fellows complained of being kept out of their own property. Is there any other society, club, or association that is equally liberal?

If in the opinion of our critic we owe everything to him, I may be entitled to ask whether we are not also under obligation to our fellows who pay their dues and dare to make their own rules. These, indeed, have been most generous and worthy of the best feelings of a liberal profession. I may add, that even at present, the council is engaged in framing rules of admission to the library for those who are engaged in literary work, no matter whether they belong to the profession or not.

Dr. Tracy says that "after considerable parley he was allowed to remain when one of the members of the academy insisted upon it." The rule of the library is "silence;" the rule of the employees is obedience to their orders. Dr. Tracy tempted them to break it.

A. Jacobi, Chairman of the Board of Trustees.

To the Editor of the Medical Record:

Sir: I note Dr. Sam'l G. Tracy's letter in the Medical Record complaining that the present rules of the Academy Library do not suit his convenience. As the gentleman is not a member of the Academy of Medicine, I fail to understand on what grounds he is entitled to any privileges whatever. He should rather be thankful for the gratuity he now receives from the academy, namely free use of the library between 9.30 A.M. and 1 P.M. Fellowship in the academy costs $20 a year, and any reputable physician in the city is eligible to fellowship. If Dr. Tracy is busy in his office all the morning he certainly ought to be able to afford to pay the regular dues.

The whole question of the Academy Library boils down to this: If a physician is too busy in the morning to go to the academy, he can certainly afford to pay the dues. If he can't afford the dues, he cannot be very busy, and therefore has plenty of time to avail himself of the privileges of the library at the hours that the fellows gratuitously offer.

Fellow of the Academy.

A NEW BILL TO REGULATE THE PRACTICE OF OSTEOTHERAPY.

To the Editor of the Medical Record:

Sir: A bill has been introduced in the Legislature of the State of New York by Senator Fitzgerald, entitled "An Act to Define and Regulate the Practice of Osteotherapy." It is Senate Bill No. 983, Introductory No. 761, and has been referred to the Committee on Judiciary, of which Hon. Edgar T. Brackett is chairman.

This bill defines "osteotherapy" as follows: "The practice of osteotherapy is defined to be a system, method, or science of healing without the use of drugs or medicine of any kind. It is based upon the proven laws of anatomy and physiology, and comprises scientific and thorough knowledge of the structure and functions of the human mechanism, to apply certain organic laws and natural remedial resources, within the human organism itself, and by means of scientific manipulations and adjustment, assist nature, in harmonious accord with its own mechanical principles, activities and processes, to recover from displacements, derangements, obstructions and pressures, and to regain normal equilibrium of form, action and function, thus restoring to the patient normal health and strength. The word "osteotherapy" is derived from the Greek ("osteon," bone, and "therapeia," nature, healing). The word "osteotherapy" is a correction of the word "osteopathy," which latter means, translated from the Greek ("osteon," bone, and "pathy," suffering) bone suffering. The word "osteotherapy" embraces the science so-called osteopathy, the practice of massage and Swedish movements to its fullest extent, and any one practising the latter sciences, under those or different names, shall come under the jurisdiction of this act."

It is difficult to imagine this as a serious effort to secure legislative enactment, for to read the definition is "to laugh;" but we must assume that the gentleman who introduced the bill was not actuated by a desire to amuse his colleagues. The measure goes on to provide for a board of examiners, appointed by the Regents of the University of the State of New York, for examination and registration fees, and so on. If physicians will write to the members of the Senate Judiciary Committee opposing this bill, its fate will not be long in doubt.

If you will publish this letter together with the inclosed reasons * why "osteopathy" and allied "pathies" should not receive special recognition, it will bring the matter before the profession, and, I believe, aid those who are endeavoring to protect our professional standards. One of the arguments used at the public hearings before our legislature is that other States have enacted laws recognizing the practices of "osteopathy," "optometry," and other peculiar methods of treating disease. I cannot believe that New York will ever enact similar laws unless some better reason than this is ad-

ıced. I do not believe that New York will enact any
s affecting the practice of the healing art unless the
dical profession will endorse them. This opinion is
result of about eight years of more or less intimate
uaintance with our legislators, and, if it is correct,
n, to use the language of the day, it is up to the medical
fession to be alive to its responsibilities.

ASONS WHY OSTEOPATHY, OSTEOTHERAPY, AND OTHER
ECULIAR METHODS OF TREATING DISEASE SHOULD NOT
ECEIVE SPECIAL PRIVILEGES.

'1. There are no methods of counteracting the results
lisease, or of remedying or correcting physical defects,
own to science, which are not known and practised by
lified and competent physicians when such methods
e in themselves any valuable properties.

'2. The practice of medicine, or, to use the more com-
hensive term, the treatment of disease, has not reached
t degree of perfection where it is possible to say with
ctness that a certain remedy is a certain cure under all
ditions. Circumstances modify conditions, and it is
y after weighing all the conditions present in a given
e, and often after consultation with experts in special
s, that the remedy can be selected and properly ap-
d; and even then, under what may seem to be the
t favorable conditions, the results are not always
isfactory. Therefore, the State, recognizing how im-
fect and uncertain the knowledge of the healing art is,
created a standard of proficiency with which all who
e the right to practise this art must comply.
that such practitioners may be able to treat cer-
diseases; not with the idea of creating certain
es of practitioners, but with the single idea that
who hold themselves out as competent to practise
healing art shall have sufficient knowledge to re-
ize and discriminate the various diseases and defects,
to be familiar with and able to apply the known
dies. The State places in the hands of practitioners
the healing art extraordinary discretionary power;
receiving this power from the State these practi-
ers are responsible to nobody but themselves for
conscientious discharge of their duties. It would be
ifestly improper for the law-making powers to confer
ileges such as these on any but the most competent,
der to make them as little a menace to the community
possible.

3. Osteopaths, or osteotherapaths, claim that the
hod they employ is not the practice of medicine. The
on, be he Supreme Court Judge or an ordinary citizen,
o claims that the practice of medicine necessarily im-
s the giving of medicine or drugs, must have a very
ited knowledge of the work of physicians. There are
y physicians who have received the privilege from the
e to practise medicine, and who would deny they were
thing but practitioners of medicine, who rarely resort
rugs in the treatment of the affections they have to
l with. Indeed, it is quite as much the function of the
ical practitioner to give advice as it is to give medi-
; to apply other forms of treatment, as bath, rubbings,
age and manipulations, as it is to apply drugs.
re is an ever-growing tendency to give fewer and fewer
gs in the treatment of disease, but no educated physi-
would be willing to undertake the treatment of any
of disease if he was denied the privilege of giving
s and medicines if they seemed to be indicated, or in-
d to be restricted in his treatment of disease to the em-
yment of any one method. Whether the treatment of
ase is the practice of medicine or not, one thing is cer-
: osteopaths and osteotherapaths desire the privilege
essed by licensed physicians, that of treating diseases.
one disease, or any particular class or type of disease;
y desire the right to undertake the treatment of all
ases, defects and infirmities indiscriminately, as phy-
ans do, except that they are willing to be restricted to
employment of one method of treatment. This, as
ady stated, is in itself sufficient to condemn them as
icating the absence of knowledge of the scientific dis-
veries of the present time. No conscientious and edu-
ed physician would be willing to submit to a restriction
this kind.

"4. The so-called theories of the so-called osteopaths or
teotherapaths, are positively dangerous. For example:
ey have recorded themselves at the hearings before the
gislature of New York and other States as not believing
the contagiousness of certain diseases, as smallpox,
arlet fever, erysipelas, and so on. With this ignorance
ey would not realize the necessity for disinfection, and
ould go directly from attendance on a case of this kind
deliver a pregnant woman, and the result might be
astrous.

"The denial of the value of antitoxins, of vaccination,
d of the necessity for isolation and disinfection, together
th the teaching of doctrines entirely at variance with
cepted scientific facts, stamps these people as positively dangerous to the community. That they should ask the State to create a standard for them less rigid than that with which physicians generally have to comply, is evidence itself that their motive is neither honest nor honorable. If osteopaths, or osteotherapaths, really and honestly believed that they were possessed of a knowledge, or had a method of treating diseases superior to the knowledge or methods of other physicians, they would not constantly endeavor to secure the legal right to employ their methods by compliance with a standard less than that already demanded by the State. The logical course to pursue would be to comply with the existing standard, and then demonstrate the superiority of their methods.

"5. Osteopaths, or osteotherapaths, claim an extraordinary knowledge of anatomy and chemistry. If such a claim is a truthful one, it does not stamp the possessors of such knowledge as competent to practise the healing art. A knowledge of physiology and pathology is even more important and necessary. It will not do to say one does not believe in the accepted views of pathology and etiology unless one has a knowledge of them, and one cannot have a knowledge of these branches unless one has devoted sufficient time to their study to acquire it. If four years of study are necessary to prepare and properly equip physicians, and osteopaths, or osteotherapaths, can secure the legal right to undertake the treatment of disease after only two years of preparation, some other class of practitioners will doubtless appear and urge, with equal reason and justice, that only one year of preparation is necessary to properly fit one to practise their method. It will not do for the State to discriminate; if any standard is necessary at all, it should be made to apply to all alike. Either this must be done, or, in justice to all practitioners of the healing art, all standards should be abolished, and the field thrown open to all comers. The latter course would be best for the doctors, but not so good for the community. The public generally can have but a limited knowledge of what is best in the way of remedies and methods in the treatment of disease. For its own protection the State creates medical laws, and, instead of lessening the requirements of these laws at the request of all sorts of fakirs who may come along, it would be better to make the requirements more rigid, and make the penalty for violation of the common law so severe and so easily enforced that quacks and charlatans of all kinds would keep clear of the State of New York."

FRANK VAN FLEET, M.D.,
Chairman, Committee on Legislation of the Medical Society of the State of New York.

Progress of Medical Science.

The Boston Medical and Surgical Journal, March 10, 1904.

Blood-pressure Observations in Surgical Cases. Report of the Committee on Research for the Division of Surgery, Harvard Medical School, January, 1904.—W. E. Faulkner, for the Boston City Hospital; J. S. Stone, for the Children's Hospital, and F. T. Murphy, for the Massachusetts General Hospital, have exercised a general supervision over this work, and have reported upon the value of the results. The Riva-Rocci sphygmomanometer was employed. The Committee on Surgical Research summarizes the results of this series of observations as follows: The value of the Riva-Rocci apparatus in determining the blood-pressure in surgical patients is limited to a comparatively small number of cases. The conditions of cerebral compression and of surgical shock produce the most marked and definite alterations in the blood-pressure. When these conditions are present, and other confusing causes of alteration in the blood-pressure are eliminated, the value of the blood-pressure determinations, as an indication for or against operation, is increased. Under other circumstances the value of these observations is at present not apparent. The adoption of blood-pressure observations in surgical patients does not at present appear to be necessary as a routine measure.

Journal of the American Medical Association, Mar. 26, 1904.

The X-Ray in Leukæmia.—E. J. Brown reports a case thus treated. His patient was a man of thirty years with the splenomyelogenous form of the disease. Iron and arsenic were given internally, while the rays were applied to the splenic region twice a week. The general condition so improved that after a while the internal remedies were discontinued, while the rays were applied daily to the spleen-ends of the long bones and sternum. After seven months all symptoms of the disease had disappeared. The author gives the results of the blood counts at various stages of the treatment.

The X-Rays in Pseudoleukæmia.—The patient of O. W. Steinward was a girl of fifteen years with the typical con-

ditions of the malady in question. She grew worse on Fowler's solution, and was exposed to the *x*-rays directed to the neck once daily. After three months of treatment, all troublesome symptoms had disappeared and the patient expressed herself as being in the best of health. As treatment progressed, the spleen increased in size. The only explanation the author can offer is that there must have been certain toxic products, liberated through the influence of the *x*-rays, which were at once taken up by the circulation, causing also acute exacerbations of ill feeling following each exposure. This condition of elevated temperature and ill feeling lasted from ten to fourteen hours, and was so severe at times that had it not been for the steady reduction of the size of the glands the treatment would have been abandoned. Six months later all the formerly enlarged glands had shrunk to their normal size but were still hard and fibrous. The general condition was excellent.

Obstruction and Consequent Distention the Cause of Appendicitis.—This proposition is advanced by C. Van Zwalenburg, who bases his views on cases seen in actual practice and on experimental appendicitis in dogs. His conclusions are as follows: (1) Simple infection does not account for the suddenness of the attack nor early severity of the pathological changes in acute appendicitis. (2) The evident interference with the blood supply is best accounted for by an increased intra-appendicular pressure. (3) Simply injecting bacteria into the appendix wili not produce appendicitis unless used in abnormal amounts and virulence. (4) Subperitoneal ligation of the appendix with a simple ligature without distention cannot be made sufficiently permanent to produce a general infection of the appendix, typical of appendicitis in the human being. (5) Experiments in dogs show that hydraulic pressure equal to the arterial tension maintained within the lumen of the appendix for a short time is promptly followed by typical appendicitis. (6) The blood supply in an extremity may be cut off with impunity for hours; but in the appendix the ever-present bacteria at once begin an infection, their entrance into the tissues being facilitated by the opening of normal and traumatic avenues by the very distention which cuts off the circulation. (7) The importance of making a complete diagnosis and prognosis during the first twelve hours of the attack is emphasized. (8) This study suggests the possibility of infections or other lesions being produced in other hollow viscera, especially in the gall-bladder, the stomach and intestines by temporary overdistention.

The Relations of Nature's Provisions for Heart Stimulation and Control to the Use of Cardiac Drugs in Acute Disease.—L. F. Bishop deprecates the use of the term "stimulant" as applied to cardiac remedies. We have but few stimulants in the true sense of the word and these are rarely used. Many drugs so-called are really only regulators. The best stimulants, such as ammonia, ether and amyl nitrite, are poor regulators, while the best regulators, such as digitalis, strophanthus and sodium iodide, are poor stimulants when a quick action is needed. Bishop declares that the misconception of the importance of stimulation as an element in recovery from disease has unquestionably led to much harm. When in a very sick person it is found that the pulse is slow, reflecting only the weakness of the patient, one should rather rejoice than otherwise. Circulatory failure does not, as a rule, take place in this direction. Primary low arterial tension without excessive rapidity is not ordinarily dangerous if let alone. Such a heart may carry on its work successfully, while if injudiciously drugged it may be so exhausted that if the stage of the rapid and feeble heart be reached, there may not be reserve force enough to carry the patient through the disease. Increase in the heart rate in disease tending to dissolution is combated only by measures influencing vitality itself. If in acute disease the patient is to be pulled through, it must be done by measures directed to the restoration of the whole body economy. Hence the value of strychnine, hydrotherapy, nutrition, and above all, of sleep. No matter how interesting the mechanical questions of the circulation may become at such times, the whole man must be treated and not the heart alone.

Medical News, March 26, 1904.

A History of Saliva, Its Physiology, Chemistry, and Pathology.—Harold M. Hays gives an interesting review of the literature on saliva. He then considers its physiological chemistry and pathology. He presents the following conclusions: There are many interesting points in connection with saliva, some of which have been worked out only "in embryo." The work on saliva has broadened its field by means of the wonderful improvement in technique. The examination of saliva may play a decided part in diagnosis when more is known of the subject. The writer is now working on tuberculous saliva. Another line of investigation is in the detection of urea in the saliva in cases of eclampsia.

Sea-bathing in Some Forms of Skin Diseases.—R. Abrahams enumerates the following diseases in which he has seen successful results from sea-bathing: Pityriasis versicolor, herpes tonsurans maculosus et squamosus, chronic eczema, and pruritus senilis. Baths in tanks filled with ocean water have resulted in utter failure to obtain any appreciable results. It must be concluded that bathing in the sea derives additional value from certain factors which the writer believes to be the following: The longer immersion which is possible, because it is more agreeable in the sea; the pounding of the billows which rubs the water into the skin; the exposure to the sun in the intervals of the dips, which dries the solids in the water into the skin; and the rolling on the sand of the beach, which helps to remove scales and other pathological débris from the skin.

Physiological and Clinical Aspects of Hydrotherapy with Special Reference to the Treatment of Psychoses.—R. D. Baker says that primarily the action of water is that of an irritant to the peripheral sensory nerve-endings and in this reflex way affects the circulation, respiration, temperature, tissue change, and secretion. The writer then describes the various methods in use in hydrotherapy, and gives an account of his work in this field among the nervous and insane. He has found the wet pack at 65° F., or the full bath at 65° to 105° F., very useful in excited cases and in insomnia. He classifies his cases as follows: Acute melancholia, acute melancholia with agitation dementia præcox, hysterica, and puerperal insanity. The patients, by this treatment become brighter and more interested in things about them. The physical condition greatly improves, the appetite increases, and with it the body weight. There is improvement in geneal muscular and nerve tone. Hygienic and medicinal measures are also continued at the same time. The various hydriatic measures adopted in a given case will depend upon the disease, the condition of the patient, and the particular result desired. Hydriatic treatment is given with good results in cases of measles, scarlet fever, and pneumonia.

Pneumatic Tourniquets, with Especial Reference to Their Use in Craniotomy.—Harvey Cushing states that the suggestion of an inflatable tourniquet doubtless originated in the use of the distensible armlet of the Riva Rocci blood-pressure apparatus. The writer calls attention to the effect of this armlet in operations on the extremities. The pressure is relatively painless, but the slow distension by shutting off the veins before the arteries causes such an engorgment as to render a clean dissection most difficult. The writer has constructed a similar armlet, broader, of less distensible rubber, and of such quality that it would stand boiling. This is connected with a bicycle pump of sufficient size, so that one or two quick strokes of the piston suffices to fill it. The tourniquet may be adjusted but not blown up until the operation is begun. During the past year, and since the writer has been using this tourniquet, eighteen of a series of craniotomies have been in a situation suitable to its use. A detailed description is then given of the writer's method of cranial osteoplastic resection. He finds this tourniquet most useful in these operations. It is narrow enough to lie well below the inferior area of the motor zone. The local part of the dressing over the wound is applied before the tourniquet is allowed to collapse, and is removed from the head.

New York Medical Journal, March 26, 1904.

The Best Time for Repairs of Laceration of the Cervix.—R. L. Dickinson advises the following course to be followed: (*a*) to suture cervical injuries at the close of labor when they seem to be the cause of post-partum hemorrhage; (*b*) to sew up all cervical tears in the first week in conjunction with the perineal operation when the pelvic floor injury is of such character that a few days' delay is desirable, and (*c*) to restore severe injuries to the cervix from the third to the tenth day after delivery.

The Use of Injections of Sodium Cinnamate in Locomotor Ataxia.—P. Bartholm advises the use of a 10 per cent solution of the drug in sterile water, begins with doses of twenty minims, gradually increased to sixty, and as a rule injects thrice weekly in the interscapular space. His results have been extremely satisfactory. He believes that the remedy benefits the organism in two ways: (1) by promoting appetite and digestion and, consequently, nutrition; (2) by setting up chemical changes in the outlying regions of degeneration, in the cells and connective tissue of the nerve substance.

Physiological Saline Solution; A Review of Some of Its Clinical Uses.—E. P. Palmer describes the preparation of the solution and enumerates as its uses the following: to com-

effects of hemorrhage, relieve shock, stimulate excre- in uræmia and puerperal sepsis, lesser toxæmia in oning from carbonic mon- and di-oxide, chloroform, r, opium and belladonna, to restore the tone of the sys- after severe intestinal fluxes, relieve diabetic coma suppression of urine, and as a local dressing for severe ns. He especially advocates hypodermoclysis, which ays has largely superseded the intravenous method. he former the fluid must first be taken up by the lym- tics and enter the general circulation slowly, the danger dden and forcible stimulation of the heart and sudden ease in the blood-pressure being avoided. There is no re- on following hypodermoclysis when done under strict tic precautions and followed by gentle massage, and it rdinarily quite as effectual as the intravenous route; as it is not so rapid in its action, it is not to be depended n in desperate cases, when immediate action is neces- . The solution should be allowed to flow slowly and age of the resulting tumor should be continued until solution is absorbed.

e Influence of Typhoid Fever on the Nervous System.— lences of the effect of the disease on the nerves are first ifest, according to C. C. Hersman, in the prodromal s and pains, especially the headache. Not infre- tly we have a weak heart action by direct effect on cardiac ganglion and nerve supply to the heart. The hoses are the initial delirium, which may be a very symptom, the febrile delirium which usually comes e second or third week, which amounts to a confused ition of the mind, a melancholia, or a violent motor ement, the low muttering delirium so common in typhoid. Convalescence may be disturbed by a de- n due to exhaustion. In the inherited neurotic cases a and melancholia may occur. Meningitis is a grave plication. Among the neuroses we find epilepsy, eria, tabes, multiple sclerosis and the so-called "ty- d" spine. Less frequently the nerves of special sense involved. Insanity is not uncommon. Soreness of eet and calf muscles during convalescence is often . The author has seen also several cases of multiple itis, the low extremities suffering more than the upper.

American Medicine, March 26, 1904.

emoval of a Pin from the Vagina Seven Months After g Swallowed.—Frank C. Hammond reports this case. patient was a woman twenty-eight years old. In the se of treatment for metritis, a pin was discovered in left vaginal wall. It finally protruded through the nal wall, and was found to be embedded in the pelvic r. The part within the vagina was seized with a mostat and pushed upward into the vaginal wall, thus ngaging the point. It was then pulled out from the inal wall. It had not undergone any change in the y. The patient remembered swallowing a pin about en months before.

Abdominal Pain.—J. H. Musser in his discussion of this ubject speaks of abdominal pain not due to disease elow the diaphragm, which occurs in: (1) Crises of comotor ataxia and other organic spinal-cord diseases; 2) Spondylitis rhizomélique; (3) Caries of the vertebra; 4) Cancer of the vertebra; (5) Aneurysm of the thoracic orta, especially located above the diaphragm; (6) Diaphragmatic pleurisy, and rheumatism of the dia- hragm; (8) Cardiac affections. In this last class the writer refers to the epigastric pain of acute pericarditis; of a congested left lobe of the liver in acute failure of ompensation; of angina pectoris. The writer believes hat pancreatitis is a more frequent affection than is enerally believed. The true significance of abdominal ain can be appreciated and life often saved by careful bservation, eternal vigilance, and breadth of view. The isappearance of pain must not inspire false hopes. For xample, in case of pain due to gangrene in appendicitis, he physician must be wary if the pain disappears. As vidence of toxæmia, a leucocyte count is of great value. The absence of pain in cases in which the other symptoms of obstruction of the bowel prevail is an indication that uch obstruction is due to paralysis, from overdistension, rom inhibition of nerve influences or from thrombosis n account of which the blood-supply is cut off.

Fatal Pulmonary Embolism Following Ascending Phlegmasia Alba Dolens.—John G. Sheldon reports three cases of this nature. He is unable to find anything in the literature that is of value on these points. His own experience leads him to believe that the ascending form of milkleg rarely occurs, but when present is far more apt to be followed by pulmonary embolism and death than is the secondary, or descending, form of the condition. In the many cases of descending phlegmasia alba dolens he has seen, he has never known of a case of pulmonary embolism to occur. The literature offers no help in reaching a conclusion as to the proportion of fatal endings in these cases. The symptoms in the writer's own cases present nothing unusual.

Bradycardia, with Report of an Unusual Case.—J. William Watson had under his care a patient of seventy-eight. His pulse was normally sixty-six. The writer when called found the patient in a very alarming syncopal, apoplectiform, or epileptiform condition; the pulse was 18. There had been two previous attacks. A few hours later he suffered another attack. This time the pulse was down to 16. For a month his pulse did not go above 32, and usually remained at 26 or 24. The patient continued in this condition about three months with pulse regular and slow. Extra exertion produced another attack. From this he recovered and attended to his business for two months. In the last attack his pulse bounded from 18 to 66. It then gradually dropped down to 18 and finally stopped altogether.

The Lancet, March 19, 1904.

Two Cases of Rodent Ulcer Treated by Radium.—The cases are reported by A. S. Green. Case 1 was that of a woman of seventy-five years with ulcer of the right ala nasi involving also the internal structures. The *x*-ray and high-frequency current did not give any definite results. The author therefore tried applications of radium bromide in a glass tube, the latter being held within the nose for from five to twenty minutes every second day. In three weeks the ulcer was well. Case 2 was that of a man of sixty-five years with rodent ulcer of the scalp. The *x*-ray gave no result. The tube of radium was used as before—held now up against the ulcer for from fifteen to twenty minutes. Seven exposures given within one month healed the ulcer.

Acute Appendicitis: Its Diagnosis and the Indications for Operation.—W. Russell's views on this topic are summarized in the following propositions: (1) Certain appendices are so formed anatomically that they of necessity give rise to trouble. (2) Interference with the drainage of the appendix is an important factor in determining inflammation. (3) The occurrence of appendicular colic may be taken as a warning that dangerous anatomical conditions exist in connection with the appendix. (4) In all abdominal cases detailed palpation should be carefully and patiently carried out. (5) Too much emphasis must not be put on the site of pain or on superficial tenderness. Palpation should be directed toward ascertaining the actual condition of the diseased part. (6) Statistics show that from 90 to 95 per cent. of cases recover without operation, and the chances against recurrence are as three to one or thereby. Therefore routine removal cannot be accepted as necessary. (7) Operate at once in any case with a history of previous attacks, also in all cases commencing with a rigor. (8) The chief difficulty lies in the early recognition of the cases in which the appendix will necrose or perforate rapidly. In this connection we should suspect cases which show constitutional disturbance with little inflammatory reaction round the cæcum but present marked tenderness on deep palpation and an ordinary degree of leucocytosis. (9) In cases which do not call for immediate operation pain may be relieved by hot or cold local applications and by a cautious and sparing use of opium or morphine or of belladonna. Lavage may give good results. (10) Medical treatment should not be relied on for more than from twenty-four to forty-eight hours if severe pain continues or an acute tenderness on deep palpation still remains. (11) Later in the disease a continuance of the local and general symptoms along with a high leucocyte count indicates the presence of pus and the necessity for operative interference.

The Early Diagnosis of Acute Intestinal Obstruction.—W. Hale White refers to the difficulty of diagnosis between certain cases of obstruction and acute appendicitis. Generally, appendicitis is mistaken for obstruction, but not of the most acute variety. It is not rare for a mistake to be made between acute general peritonitis and intestinal obstruction, and this is not surprising, for strangulation of the bowel renders possible the passage of bacteria through it, and therefore many cases of acute obstruction quickly become complicated by acute peritonitis; hence, it follows that the difficulty of diagnosis is often less, the earlier the case is seen. Speaking generally, absence of fever and of leucocytosis indicates obstruction; so also rapid abdominal distension, especially if peristalsis can be noted in the intestinal coils; early and urgent vomiting quickly becoming stercoraceous is in favor of obstruction; the pain is often paroxysmal in obstruction, the abdomen is not board-like or very tender, and there is no cutaneous hyperæsthesia; the patient does not lie in the usual attitude of peritonitis but may bend forward, doubled up by the pain, and the abdomen moves with respiration until later in the disease than is the case with acute peritonitis. But it is essential to bear in mind that every one of these

symptoms which have been mentioned as generally indicating obstruction may be met with in peritonitis in which there may be complete absence of the passage of fæces and flatus by the bowel. Volvulus is the form of intestinal obstruction which most resembles acute peritonitis. Other conditions mistaken for intestinal obstruction are acute hemorrhagic pancreatitis, perforation or rupture of any hollow viscus, thrombosis and embolism of the mesenteric vessels, intestinal biliary and renal colic, twisted pedicle of pelvic tumor, and hysteria. In regard to operation, it should be remembered that the early symptoms of acute intestinal obstruction are caused by strangulation of the bowel and not by its obstruction. Usually speaking, there are no acute symptoms unless there is strangulation and the symptoms of this are sudden, agonizing pain, often paroxysmal, referred to the umbilicus, frequent, early, distressful, and severe vomiting, a rapid, feeble pulse, an ashy, pinched countenance, a normal or subnormal temperature, and collapse. If there is great and rapid distension in addition to symptoms of strangulation, we infer a volvulus; if there is history of chronic obstruction—*e.g.* that due to malignant growth in the large intestine—the distended bowel behind the obstruction has become kinked or strangulated in some way; there may be other evidence of intussusception; or if, as is usually the case, we decide none of these are present and there is no external hernia, then, arguing from the experience of the post-mortem room, we learn that the small intestine is almost certainly the seat of the strangulation, but we cannot from the foregoing locate the exact site of the trouble.

British Medical Journal, March 19, 1904.

Venesection in Opium Poisoning.—William A. Caskie declares that when all other efforts have failed to rouse the patient from a comatose condition, venesection may restore the patient to consciousness by the abstraction of some of the poison circulating in the blood, thereby preventing its reabsorption, and relieving in some degree the paralysis of the nervous system. This treatment has met with great success.

Two Cases of Lung Disease Treated with the Emanations from Thorium Nitrate.—Gordon Sharp gives a brief account of two cases of lung diseases which were greatly benefited by inhalations from thorium nitrate solution. A bottle which has a capacity of 500 c.cm. is filled with water in which is dissolved 100 grams of thorium nitrate. The solution is ready for use after standing for twenty-four hours. The gaseous emanations then have time to collect. The bottle consists of an ordinary gas-washing bottle modified to suit the special conditions. The writer does not claim for the emanations a specific action, but he wishes to call attention to the beneficial results of this treatment. The breathing exercises, even alone, must be good.

Some General Results of Affections of the Nose and Nasopharynx.—W. S. Syme speaks of the effects of disorders of the nose and nasopharynx on the general health. The secretions which pass into the stomach as a result of these diseases are bound to influence the health. The nervous or mental element must also be considered in these cases. In cases of chronic ill health, associated or not with gastric derangement, it is advisable to include among the possible causes certain affections of the nose and nasopharynx, especially those giving rise to a discharge of a mucopurulent or purulent character. The patient may even be unaware of the existing nasal trouble. Careful rhinoscopic examination may be necessary to discover it. Treatment directed to the nose should be looked upon rather as a reinforcement of, than as an alternative to, the more usual methods.

Some Points in the Treatment of Hæmoptysis at a Sanatorium.—J. Penn Milton classifies hæmoptysis as follows: Occurring early in the disease; when the disease has been present for some time and the physical signs reveal a decided extent of consolidation; late in the disease when cavitation is present; in any stage in plethoric subjects. In the first class, the treatment depends upon the amount of blood lost. Exercise is often indicated, but it should be short of fatigue and breathlessness. In the early cases, medicines beyond a saline purge are usually not necessary. In the second-class, treatment should be directed to strengthening the lowered vitality, and to improving nutrition by sanatorium treatment and forced dieting. If fever is present, it must be treated by rest in bed, if high, and by rest on a *chaise longue* in the bedroom if slight. The object to be attained in treatment of the third class is to favor the formation of a thrombus, which is gained by (1) lessening the frequency of the heart beats; (2) resting the lungs as much as possible; (3) lowering the blood-pressure. The first two can be effected by seclusion and absolute rest. The administration of saline purgatives will lower the blood-pressure. After severe hemorrhage the patient must remain in bed till the sputum has been free from blood for at least a week. In the fourth class, the treatment indicated is (1) to lower the blood-pressure; (2) a full amount of exercise, provided there is no contraindication, such as fever; (3) a modified diet, in which vegetables, especially green ones, play a large part, a minimum amount of meat, and alcohol should be forbidden. Wind exposure is always liable to bring on an attack of hæmoptysis. Each case must, of course, be treated individually.

Deutsche medizinische Wochenschrift, March 10, 1904.

The Side Effects on the Ear of Some Drugs.—Schwabach describes two cases in which ear symptoms occurred which remained inexplicable until it was discovered that the patient was taking medicines for other conditions. The first was that of a young woman suffering from obstinate tinnitus, deafness, rhinitis, and blepharoconjunctivitis. Treatment proved unavailing to effect more than temporary relief till it was learned that she was at the same time taking Fowler's Solution for a chronic eczema. Stopping the drug cured the symptom complex. The second patient was also a woman, who came under treatment for acute pneumonia. She suffered from extreme tinnitus and deafness, which it was afterward discovered were due to large doses of salipyrin taken at the beginning of the sickness. The author says that fluid extract of ergot often brings relief in these conditions, though there appears to be no pharmacological reason for its doing so.

The Treatment of Fractures of the Lower Jaw.—Kerstin discusses the treatment of this difficult lesion and describes the appliances that have been devised to secure immobilization of the fragments. The requirements to be fulfilled by any form of dressing are that it shall lead to perfect healing and that the function of the jaw be interfered with as little as possible during the treatment. For uncomplicated cases a simple external splint with bandage passing over the top of the head often suffices. Wiring the fragments is often very satisfactory but cannot be done when comminution exists, and always condemns the patient to loss of function of the jaw during the process of repair. Various forms of dental splint are described, but these are nearly all either painful to apply, are insecure, or are open to the objection of not permitting cleansing of the mouth and therefore lead to great discomfort to the patient. The author has devised a splint of caoutchouc, reinforced with wire, which embraces the teeth on both sides but allows their crowns to lie exposed so that mastication is possible. Exact adaptation to the irregularities of the teeth and easy removal and reapplication are secured by making portions of the splint hinged so that it can be opened up for introduction and closed when in position.

The Significance of the Fatty Tissue in the Pathology of the Knee-joint.—Hoffa describes a form of knee-joint disease which has not received the attention it deserves. It consists in an inflammatory hyperplasia of the fatty tissue underlying the ligamentum patellæ, in consequence of which it becomes permeated with strands of tough, fibrous connective tissue. The starting point of the affection is nearly always a trauma, usually acute, though it may be chronic, whereby the fat tissue in question is irritated and a proliferative inflammation is induced. The swollen tissue thus bulges into the joint and is constantly pinched between the femur and tibia, thus causing pain and leading to aggravation of the inflammatory process through the repeated irritation. The symptoms are much like those of a movable cartilage in the knee, but the differential diagnosis may be made owing to the characteristic appearance of such a joint. No fluid is present, but below and on either side of the patella a rather soft, semi-fluctuating swelling is visible and palpable. The treatment comprises palliative measures, such as moist compresses, massage, and compression. If these are ineffectual the offending mass of fat can easily be removed through a longitudinal internal incision. The author reports on seven cases cured in this way.

Berliner klinische Wochenschrift, March 7, 1904.

The Treatment of Ozæna by Paraffin Injections.—Fliess, actuated by the view of numerous writers that ozæna is largely due to abnormal size of the nasal passages, has tried the paraffin method of Gersuny to reduce the lumen of the canals. The method is as follows: The nasal cavity is carefully cleansed and all crusts removed, the inferior turbinated, the floor of the naris and the septum are then cocainized. Meantime an assistant has been preparing the paraffin and syringe, and the mess is injected into one or both ends of the lower turbinated, as seems necessary. If the lumen is still too large a little paraffin may be injected into the septum also. The author has made thirty-two injections in twelve cases with very satisfactory results. No cure has been obtained or hoped for, but the improve-

ment has been greater than with any other method. The crusts have disappeared to a greater or less degree, the secretion is diminished and the odor has been reduced so much that in some patients it cannot be noticed and in others is very slight.

The Intensity of Cholera Amboceptor Formation after Alcoholic Intoxication and Mixed Infections.—Friedberger attempts to solve the problem of the value of alcohol as a therapeutic agent in infectious diseases by testing the antibody formation on the injection of dead cultures of cholera vibrios into rabbits previously treated with alcohol. The antibody formation was measured by determining the amount of serum sufficient to protect a guinea-pig against ten times the fatal dose of cholera vibrios. By this method it was found that a single dose of alcohol given at the same time as the immunizing injection serves to increase the antibody formation two and one half times. This is in accord with the beneficial results observed by clinicians in the administration of alcohol early in infectious diseases. On the other hand, the animals subjected to chronic poisoning with alcohol produced a serum sixteen times weaker in antibodies than that of the control animals. This bears out the observation that in epidemics it is the alcoholics who succumb first. Animals injected with mixed cultures of cholera and other organisms, such as typhoid bacilli or those of rabbit septicæmia, produced a serum from six to forty times weaker in antibodies than that of the control animals who had received only cholera culture.

Münchener medizinische Wochenschrift, March 8, 1904.

A Case of Traumatic Pulmonary Hernia without External Injury.—Riebold describes this case, which belongs to the curiosities of medicine. The patient fell heavily to the ground, his chest striking against a block of iron. Several ribs were fractured, and ten weeks later a hernial protrusion of the lung several inches in diameter was sometimes observed in the space between the injured second and third ribs. The protrusion appeared only when the intrathoracic pressure was raised by forced expiration, coughing, stooping, etc. Examination of the intercostal space showed that the fractured ribs had separated somewhat, and that the intercostal muscle had been torn through, so that the lung tissue could be palpated directly through the gap. The symptoms occasioned were local pain and dyspnœa, but showed a tendency to steady diminution of intensity.

A Case of Complete Rhinoplasty from the Arm.—Habs describes an interesting method of applying the Tagliacotian procedure for rhinoplasty. The patient was a young woman who had suffered complete destruction of the nose through syphilis. Wishing to avoid the further deformity which the scars attending the Indian rhinoplasty impose, the author decided to attempt the Italian method with the addition of including a strip of bone with the flap from the arm. At the first sitting a large tongue-shaped flap was stripped back from the dorsal surface of the left forearm. A strip of bone was chiseled from the ulna, severing all connections except a periosteal bridge. On this, as a hinge, the strip was turned over so that its raw surface came in contact with the under surface of the flap. The large denuded area was skin-grafted and the flap allowed to drop back over the grafts till the second step of the operation was done a month later. The flap was raised, the periosteal bridge divided, and the projecting end of the flap turned down over the periosteal surface of the strip of bone, which was thus, so to speak, wrapped up in the flap. At the third sitting the free end of the flap was sutured to the properly denuded site on the face and the elbow fixed against the forehead by a large plaster-of-Paris dressing. Three weeks later the flap was severed from the arm, and after several minor procedures intended to improve the shape of the organ a very satisfactory nose resulted. The original feature of the operation consists in the manner of providing a bony support for the new nose, which now, over half a year after the operation, shows no evidence of secondary changes.

Primary Anæsthesia.—Hofmann describes his method of performing minor operations, painful examinations, etc., in the very brief period of anæsthesia which appears shortly after the beginning of the inhalation of ether. Two methods of obtaining this primary anæsthesia in its most advantageous form are described. One plan is to give a hypodermatic injection of one-sixth to one-third of a grain of morphine one hour before the operation. At the proper time the narcosis is begun by placing a gauze mask over the face and slowly dropping ether on it from a drop bottle. At the same time the patient is told to count backwards, beginning at 200. The dropping is begun as soon as the respiration has become even and regular, and the proper time for operation usually arrives before one hundred has been reached. The presence of the proper stage of anæsthesia is indicated by interruption of the counting, deep respiration, and complete muscular relaxation. The duration of the anæsthetic period is very variable, but usually covers ten to twenty seconds. In every-day work it is preferable and more convenient to omit the morphine and in its place to have recourse to the addition of a few drops of chloroform. After the usual precautions in regard to tight clothing, foreign bodies in the mouth, etc., the patient is placed in the recumbent position and the ether inhalation begun just as in the other case. Primary anæsthesia often appears in from one to three minutes, but if it does not at the expiration of this time, chloroform is dropped on the mask in the same way, and usually produces the desired effect in a very short space of time. The patients are completely conscious as soon as the mask is taken from the face and are able to walk home. Vomiting very rarely occurs.

French and Italian Journals.

Faborable Results of Hepatic Opotherapy in Cirrhosis of the Liver.—Créquy reports the case of a man suffering from a severe degree of hepatic cirrhosis. The lack of success which had attended the classic treatment of this patient determined the writer to try hepatic opotherapy. The patient's condition was precarious. He was suffering from hemorrhoids which bled profusely. Milk diet was continued, with one egg a day, and a small quantitv of pork liver; every morning 1 gram of hepatic extract in a cup of milk was given. Potassium nitrate, .50 gr. was given. The hemorrhages ceased. The œdema disappeared. The ascites did not reappear; after the first drainage the appetite improved; four months after the last drainage the patient could attend to his usual occupations. Only one symptom persists—tympanites.—*Le Bulletin Médical*, March 12, 1904.

Experimental Studies of the Mixed Infections.—G. B. Simoncini and F. Pino have made experiments with reference to the reciprocal influence of the different bacteria on one another. They made use of the protein of the bacillus prodigiosus, and its influence on different bacilli, such as the diplococcus of Fraenkel, bacillus of typhoid, bacillus coli, bacillus of diphtheria, staphylococcus pyogenes aureus, etc. These bacteria are rendered more rapid in their development and growth by the bacillus prodigiosus, outside of the body. Experiments were made on rabbits and guinea-pigs. The writers conclude that the protein of the bacillus prodigiosus injected into animals increases the virulence of the disease bacteria present in the body. The protein of bacillus prodigiosus, if injected at the same time and place as the attenuated culture of the bacillus, always causes the death of the animal, by acting directly on the bacteria and increasing their virulence. If injected in another location, the protein of bacillus prodigiosus exerts its action upon the animal by lessening its power of resistance. Their conclusions are that the protein of bacillus prodigiosus added to the culture medium renders the development of all the pathogenic bacteria more rapid, with the exception of the bacillus of anthrax, on which it has no effect.—*Giornale Internazionale delle Scienze Mediche*, February 29, 1904.

Vaginal Cæsarean Section and a New Application of It.—Alessandro Regnoli gave an account at the Fourth International Congress of Gynecology and Obstetrics of four cases on which he has operated by cæsarean section through the vagina. The first was a case of eclampsia in the eighth month, mother and child both living. The second was a patient who had had a bad delivery in a difficult labor, resulting in rupture of the cervix and posterior vaginal fornix. A hæmotosalpynx and hæmatometra had formed and had existed for over a year without relief. An operation was done by which the patient was relieved and made comfortable, but it was impossible to restore the uterus to a normal form. The patient disappeared and returned later with a six months' and three weeks' pregnancy. Delivery by the normal passages was impossible. A cæsarean section by the vagina resulted in a recovery for the mother and a child which lived for twenty-five days. The third was a case of autointoxication from a fœtus dead for thirty-five days, but remaining in the uterus. The cervix was so œdematous and tender that it was impossible to dilate. Cæsarean section saved the mother. The fourth case was one of hemorrhage at the sixth month, resulting from the detachment of the placenta by an accident. It was impossible to await dilatation on account of the severe hemorrhage. A cæsarean section saved the mother's life. In this operation the writer introduced a method of procedure different from that of Dürssen; he incised the uterine muscle only posteriorly. The advantage is that in case of another pregnancy the uterus is stronger than where it was incised both posteriorly and anteriorly.—*Il Policlinico*, February, 1904.

Book Reviews.

THE SELF-CURE OF CONSUMPTION WITHOUT MEDICINE. By CHARLES H. STANLEY DAVIS, M.D., Member Conn. State Medical Society, etc. Pp. 170. New York: E. B. Treat & Co., 1904.

BOOKS on this topic are following in rapid succession. The present one, written obviously for the laity, goes over familiar ground, and outside of some of the statements on strictly medical matters which are rather on the "scare headline" order, seems to go into the matter of tuberculosis with sufficient accuracy to be commended. Of particular excellence are the chapters on exercise and diet.

LA RHINOPLASTIE. Par CH. NÉLATON, Chirurgien de l'Hôpital Saint-Louis, ancién Prosecteur de la Faculté des Hôpitaux. Avec 391 figures dans le text. Paris: G. Steinheil, 1904.

THIS exhaustive monograph forms part of the "Traité de Médecine opératoire et de Thérapeutique Chirurgicale" published under the direction of MM. Berger and Hartmann. Part I is comparatively short, occupying only seventeen pages, and is devoted to the consideration of deformed noses. The three main causes assigned are congenital malformations, recent and old traumatisms, and hypertrophic acne. Seven different operations for the relief of the condition are described. Part II is devoted to the consideration of destruction of the nasal tissues by such causes as trauma, gangrene, congenital absence, freezing, tubercle, syphilis, and malignant disease. A further subdivision is made into cases of partial and complete destruction respectively. Chapter IV of this part is given up to the general technicalities of the various operative procedures; Chapter V to the methods of replantation, prosthesis, transplantation, and flaps. Then follow in succeeding chapters descriptions of literally scores of operations under the names of their various originators. These are illustrated by diagrams showing positions of incisions, sutures, etc., and a considerable number of plates is inserted, giving the appearance of actual cases before and after operation. Under each heading a few remarks are inserted discussing the operation of choice in various conditions. The general tone of the work is scholarly, and it represents an enormous amount of research into the history and development of this special field of surgery. It is suggestive of the expansion of modern surgery that such an amount of strictly pertinent material can be brought together bearing on one special class of lesions.

BIOGRAPHIC CLINICS. Volume II. The Origin of the Ill Health of George Eliot, George Henry Lewes, Wagner, Parkman, Jane Welch Carlyle, Spencer, Whittier, Margaret Fuller Ossoli, and Nietzsche. By GEORGE M. GOULD, M.D., Editor of *American Medicine*, author of "An Illustrated Dictionary of Medicine, Biology, etc.," "Borderland Studies," "The Meaning and Method of Life," etc. Philadelphia: P. Blakiston's Son & Co., 1904.

THE author of these speculations on the cause of the poor health of the persons mentioned on the title page throws the responsibility for this second volume on the reviewers who, he says, neglected to give to their readers a clear and satisfactory statement of the thesis, facts, and arguments of his first book. As a matter of fact, the reviewers devoted more space to a consideration of Dr. Gould's first volume of "Biographic Clinics" than they are wont to give to much more important works. The theme was a novel one, and the originality of the book was in refreshing contrast to the dry repetitions of many of the works that find their way to the medical reviewer's table, and so it received long, and in some cases rather flattering, notices, but apparently not long enough or flattering enough to please the author. The present book should be more or less familiar to readers of periodical literature, as most, if not all, of the chapters have been published during the past year in medical journals. The plan of treatment of the theme is the same as in the former volume. The author culls from the published biographies all references to the ill health of the subjects, and proves thereby, to his own satisfaction, that the stomach troubles, the headaches, the insomnia, and, in Nietzsche's case, the insanity, were the direct and necessary consequence of not wearing properly fitted glasses. The argument is superficially convincing and the reader's hopes rise as he turns over the pages and the surety forces itself upon him that at last there is relief in sight for his headaches and stomachaches and queer feelings. But—alas and alack! there is an appendix—and we all know the painful possibilities of the appendix. Dr. Gould's appendix is entitled, "Sixty-eight Reasons Why 'Glasses Did Not Give Relief,'" and before mastering even thirty-four of these reasons our hopes are dashed to the ground—what is the comfort in being told that the cause of all your woes is known and then learning that there are three-score reasons and eight why you cannot hope to have that cause removed? It is a brilliant example of the "hedge," and no one in the face of it can disprove the author's thesis, for it can never be proved that at least one of those sixty-eight causes of failure to relieve the morbid condition by glasses is not operative in any given case. One of these "reasons" well illustrates the author's fondness for unsubstantiated statement. He says glasses may have failed to give relief because they were prescribed by an optician instead of by a physician, and then makes the absurd and altogether wild assertion that "no optician ever prescribed a scientifically correct pair of lenses." We are no friend of the optician, and believe that none but legally qualified physicians—and more than that, none but those who have made a special study of ophthalmology—should be permitted to prescribe glasses. But when one asserts that no optician has ever, even by chance [and in the simplest cases, prescribed a scientifically correct pair of glasses, he betrays an intemperance in statement that shows him to be unfit for the self-assumed part of a teacher and preacher. Dr. Gould writes fairly well and his book is entertaining, but it cannot be taken seriously. The author is a faithful, if unconfessed, disciple of Ranney, but he has not advanced the cause of spectacles one diopter beyond where his predecessor placed it. He has industriously tilled the field which Ranney ploughed, but there's nothing growing.

A SYSTEM OF PHYSIOLOGIC THERAPEUTICS; a Practical Exposition of Methods, other than Drug-giving, Useful for the Prevention of Disease and in the Treatment of the Sick. Edited by SOLOMON SOLIS COHEN, A.M., M.D., Senior Assistant Professor of Clinical Medicine in Jefferson Medical College; Physician to the Jefferson Medical College Hospital and to the Philadelphia, Jewish, and Rush Hospitals, etc. Volume VII, MECHANOTHERAPY AND PHYSICAL EDUCATION, Including Massage and Exercise. By JOHN K. MITCHELL, M.D., Fellow of the College of Physicians of Philadelphia; Physician to the Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases; Assistant Neurologist to the Presbyterian Hospital of Philadelphia, etc., and PHYSICAL EDUCATION BY MUSCULAR EXERCISE, by LUTHER HALSEY GULICK, M.D., Director of Physical Training in the Public Schools of Greater New York; President of the American Physical Education Association; Chairman of the Physical Training Committee, Louisiana Purchase Exposition; Chairman of the National Basket-ball Committee, etc. With special chapters on Orthopedic Apparatus, by James K. Young, M.D., Professor of Orthopedic Surgery in the Philadelphia Polyclinic; Assistant Orthopedic Surgeon to the Hospital of the University of Pennsylvania, etc.; On Corrective Manipulations in Orthopedic Surgery (including the "Lorenz Method"), by H. Augustus Wilson, M.D., Clinical Professor of Orthopedic Surgery in Jefferson Medical College; Orthopedic Surgeon to the Philadelphia Hospital, etc.; and on Physical Methods in Ophthalmic Therapeutics, by Walter L. Pyle, M.D., Assistant Surgeon to Wills Eye Hospital, Philadelphia. With 229 illustrations. Philadelphia: P. Blakiston's Son & Co., 1904.

THE very complete and explanatory title of the latest volume of this now well-known and prized system of nonmedicinal therapeutics, relieves the reviewer of the necessity of describing the scope and character of the book. Like the other volumes of the series, this is independent of its fellows and is really a special treatise on exercise and massage and the morbid conditions which can be prevented, ameliorated, or cured by these means. The authors are all men of practical experience in the subjects of which they treat, and write with the authority and moderation of true experts and not mere faddists. The chapters on the various physical exercises are especially valuable, dealing with the subject, as they do, from the standpoint of the physician, and may well substitute the books gotten out by nonmedical "professors" of physical culture, most of which contain a mixture of good and bad teaching so inextricably interwoven as to render them very unsafe guides to either physician or layman. The orthopedic sections are also worthy of commendation—indeed the entire work is so praiseworthy that it is unfair to pick out any part for special mention. We would, incidentally, take exception to the editor's preface where the entire credit for the recognition of eyestrain as a factor in the production of nervous disorders is given to Philadelphia ophthalmologists and neurologists. While not ignoring (who can ignore?) the furious riding of this hobby by the Philadelphia author of some entertaining biographies, we have an indistinct impression that something of the sort was said many years ago by Ranney of New York, and if credit is due anybody for this exaggeration of a minor etiological factor in epilepsy, headache, and various less serious neuroses, we claim no small share of it for the New York physician. However, this is another story, and detracts in no way from the value of a very useful book.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held March 4, 1904.

DR. ROBERT T. MORRIS, IN THE CHAIR.

nd-bearing Stumps of the Thigh, Knee, and Leg.—Dr. LEXIS V. MOSCHCOWITZ presented these cases. He said was not necessary to go into the minute histories of these ses. The conditions requiring the amputations were in e first case sarcoma, in the second, Raynaud's diseases d, in the third, recurrent tuberculosis of the ankle-joint. he osteoplastic method was used and, in all the cases, e results were very good. The ends of the stumps would and pressure and handling without pain and were, in ct, absolutely painless in every respect.

Dr. R. H. M. DAWBARN thought the thigh most justified Bier operation. In operating upon the thigh he believed best to begin by hamstringing the patient, as in this way l the five muscles retracted as much as possible, and then e could get a stump without empty spaces. Two or ree works on surgery made the statement that some of e muscles retracted as much as one-third the length of e thigh.

Dr. CHARLES A. ELSBERG said he had seen Dr. Moschcoitz operate, and he considered that much of his success as due to the firmness with which the dressings were pplied. The great danger with these flaps was from emorrhage between them, which was apt to be followed y necrosis of them. This operation could not be done in l cases. In diabetic cases and in cases of gangrene such operation would be done at a great risk.

Dr. MOSCHCOWITZ, in closing the discussion, said that an steoplastic operation was indicated in every case in which apidity was not demanded and was certainly not applicable in the diabetic and gangrenous cases. He had performed nine operations and in only one instance was it ecessary to remove the flap for necrosis. He thought he Gritti operation an ideal one and used it whenever possible, but it was more complicated than the osteoplastic. The Bier stump seemed to be as painful as those made by he usual methods.

Floating Cartilage of the Knees; Arthritis Deformans.—Dr. H. D. COLLINS presented a young maid who, two years go, had severe pain in the left knee and at times the knee would catch in the typical way. She also had some disturbance with the right knee. The patient said that an operation had been performed in Albany and a floating cartilage found. The right knee grew worse and in January last she presented herself. Examination revealed no loose cartilage and there seemed to be a pedicle on the outer side of the right femur over the condyle. Upon opening the joint a number of small rice-like bodies were removed. There were all the evidences of an arthritis deformans. In several places on the femur and tibia there were tongue-like cartilages which were similar to the rice-like bodies thrown off. Since the operation on the right knee the left was beginning to give further disturbance.

Neuralgia of the Musculospiral Nerve Following Fracture of the Humerus.—Dr. B. T. TILTON presented a patient forty-two years old, who had a simple fracture of the humerus, which was set by lateral splints of plaster Paris with good results. In December he had intense pain in the region of the musculospiral nerve and for two or three weeks he was treated with counter-irritants, hot baths, massage, etc., without relief. Although the patient was not nervous or hysterical, his sufferings were so intense that operation was resorted to for his relief. Cutting down upon the nerve it was found that the nerve had no connection with the callus, but was imbedded in fibrous tissue which compressed it. The nerve was dissected out for from two to three inches and there had been no further pain and no paralysis. The amount of callus thrown out was extremely small. The case seemed to be interesting because of the extreme neuralgia, without there being any communication between the nerve and the callus.

Dr. A. ERNEST GALLANT thought this was a case for early massage, as this would have done away with the exudate and so avoided the formation of the fibrous tissue. He was of the opinion that massage of the proper kind was not sufficiently employed, and that most students and nurses to whom this work was entrusted did not do it intelligently, and, therefore, the results were not what they should be with intelligent and skilful manipulation. He thought it to be a good plan to have young physicians take up massage while getting a start and learn to do this intelligently.

Dr. JOHN F. ERDMANN thought there were some evidences of paralysis still, as the patient had no grip to speak of.

Dr. A. A. BERG thought the result was very good for a fracture so near the tuberosity of the humerus, and suggested that possibly the fibrous tissue was due to the clot following the hemorrhage; in such a case massage would have made little difference in the result obtained.

Dr. TILTON said that there was no injury to the joint. He thought the disturbance of motility was due to the prolonged treatment, as the arm had been kept in a flexed position for a long time. The slight wrist-drop that was present he believed would disappear in time. While he was in favor of massage, he did not think the trouble in this case was due to lack of massage.

A Case of Traumatic Common Femoral Arteriovenous Aneurysm.—Dr. WARREN S. BICKHAM read this paper, reporting a case of traumatic common femoral arteriovenous aneurysm which had been unsuccessfully treated by a new method of compression, but which was finally cured by the proximal ligation of the external iliac artery extraperitoneally. The patient was a young negro, twenty-three years old, of athletic build and otherwise healthy, who was admitted to the wards of the Charity Hospital, New Orleans, in 1897, presenting a small, prominent, pulsating tumor, of somewhat oval outline, and about 5 by 6.5 cm. in measurement, seated over the course of the common femoral artery and vein, with a marked vibratory thrill and a murmur, the pulsations ceasing when compression over the external iliac artery was made and without any material change in the contour of the tumor. Ten days prior to admission he had been shot by a pistol, the ball entering the outer aspect of the left thigh about on a level with the spine of the pubic bone, and ranged inward across the front of the thigh. After a few days he noticed the enlargement and walked unaided to the hospital complaining only of the presence of the tumor. A diagnosis of traumatic arteriovenous aneurysm involving the common femoral artery was made. Within two or three days after admission, the patient, in the presence of a male nurse, urinated the pistol-ball which had inflicted the wound. The patient had complained of no symptoms referable to the ball in the bladder. It was not plain by what route the ball entered the bladder. Although realizing the inefficacy of the methods of pressure advocated, these, nevertheless, were tried. It was next decided to ligate first the external iliac artery proximally. This was readily done, and at the end of seventeen days the patient left the bed and no return was noted in the circulation in the aneurysm. The tumor had disappeared.

In the present light he questioned whether this would have been the best procedure. The risk of gangrene and even death following the ligation of the larger arteries and veins were well known, and the statistics of both pre-antiseptic and antiseptic days showed this. In Van Buren's report of 7 cases of ligation of the external iliac or common femoral artery for arteriovenous aneurysm gangrene followed in all. Curtis collected 51 cases of arteriovenous aneurysm in general treated by ligation, of which 23 died, 8 were cured, 2 improved, 18 unimproved, and gangrene occurred in 11 cases. Bilroth

found he had secondary hemorrhage in 50 per cent. of all cases of ligation of large vessels when done in continuity. Murphy reported 22 ligations of the femoral artery and vein with gangrene in 12. He had collected 178 cases of ligation of the femoral artery alone, with gangrene in 25. He also reported 31 ligations of the common femoral artery for aneurysm, with hemorrhage in 60 per cent. and death in 40 per cent. From these figures it was clear that many lives were lost through the cutting off by ligature the main blood-supply of the parts. Recognizing, therefore, the present greater frequency of arteriovenous aneurysms, and the large proportion of disastrous results following ligation of the larger vessels, it would seem wise to devise some more satisfactory method of treating this form of aneurysm. He was not aware that the Matas operation had been performed in cases of arteriovenous aneurysm, and he suggested the application of this more modern method of operating provided conditions were favorable. If the arteriovenous aneurysm were of the varicose type he said he would be inclined to follow the Matas method, namely, after temporarily controlling the circulation, laying open the aneurysmal sac, ligating both arterial and venous openings into it, and closing them off by fine chromic gut Lembert sutures applied interruptedly, followed by obliteration of sac in his characteristic manner of suturing the roof, including the overlying parts, to the floor.

If the arteriovenous aneurysm were of the aneurysmal-varix type and the conditions were favorable, a modification of the Matas operation was feasible. The modification he suggested was to make a longitudinal incision through the enlarged and varicose vein for as limited an extent as would seem to offer approach to the opening into the vein, and so placed as to lie directly opposite the communicated opening of the artery. The lips of the wound should be then retracted, thus exposing the interior of the vein and the arterial communication, and the opening of the artery into the vein should be sutured in the usual Matas manner, and then the incision in the vein closed by a continuous lateral suture of, approximately, the Lembert type. Owing to the fact that, in aneurysmal varix cases, foreign material would be left in contact with the venous current by this manner of suturing (this did not apply to the varicose aneurysm cases), he said it seemed to him well to use very fine catgut and tie small closely cut knots, or else to bury in the row of interrupted Lembert sutures, closing off the arterial opening, by means of a continuous buried suture introduced from without entirely through the vein at one of the angles of junction of artery and vein, passing in continuous Lembert fashion above the interrupted sutures, through part of the thickness of the wall of the vein, and out through the entire thickness of the vein at the opposite angle of junction of artery and vein, and so placed that the entire suture throughout its length and its points of entrance and exit, to and from the vein, were also buried.

In cases of varicose-aneurysm type in which both the arterial and venous circulation could be controlled proximally to the sac, and the sac exposed by dissection, the sac might, in appropriate cases, be excised up to very near the arterial and venous openings into it, and these openings then closed by a row of interrupted Lembert gut sutures, followed by a second burying-in row through the free margins of a small portion of the sac left around the jug-like opening into the artery and vein. He said that in those cases of aneurysmal varix type in which both the arterial and venous circulation might be arrested proximally to the arteriovenous communication, and this site of communication exposed by dissection, the artery and vein might, in appropriate cases, be severed from each other by an incision through the connecting opening, made parallel with artery and vein, and these openings closed by lateral ligation with fine gut or silk. The openings left by the incision of the connection between artery and vein was, in the aneurysmal varix, less jug-like and there was less free margin than in the varicose aneurysm. The range of dealing with vessels by methods of suturing had been much increased during the past few years, and he said that Dörfler had demonstrated that suture material could be passed safely through all the coats of an artery and vein without producing thrombosis. Portions of arteries have been excised and the integrity of the vessel established by circular arteriorrhaphy.

Dr. R. H. M. DAWBARN said that Dr. Bickham's method constituted a true advance. It was possible, however, that many cases of gangrene in the past were due to lack of antisepsis as well as to the cutting off of the blood supply. The Matas method could not be applied to all cases.

Dr. A. A. BERG asked why the external iliac artery was tied at the time of operation.

Dr. BICKHAM replied that this was done because the field was so much encroached upon.

Dr. ELSBERG considered the suggestion good, but when arteriovenous aneurysms were seated in the neck with the dilated veins extending into the skull where it was impossible to make compression of the vessels, this method could not be applied.

Dr. BICKHAM replied that individual cases must determine the applicability of the Matas method. He had applied it chiefly to the extremities. In the case cited digital compression had been tried without avail. He called attention to the fact that his statistics covered both the preantiseptic and antiseptic operations.

Technical Errors in the Use of Rubber Gloves.—Dr. HOWARD COLLINS read this paper. He reviewed the history of the rubber glove since it was first suggested some six or eight years ago, together with the arguments both *pro* and *con* which had furnished much animated discussion until, at the present time, the consensus of opinion was generally in their favor, and surgeons had adopted the glove as having distinct advantages over the naked hand. There were, however, many technical errors in their use, due both to carelessness and lack of thought. He believed a correct routine of their use should be a matter of habit. The surgeon washes, rinses, and dries his hands, making them ready for the gloves. The possibility that this procedure has not rendered his hands perfectly aseptic led to the use of gloves. Yet the surgeon took the left glove in his right hand and adjusted it with his right hand; he then took the right glove and adjusted it with the left hand, which had been possibly infected from an imperfectly cleaned hand. This was a defective method. Another defective method was to throw the gloves into bichloride solution and draw them on wet; and here the drippings from the wrist and from a possible puncture would carry the perspiration and detritus from the hand into the wound. The gloves should be put on dry, powdered with starch or lycopodium. They should be turned inside out, placed in the boiler for ten or fifteen minutes, dried between sterilized towels; the upper towel should then be turned back and the gloves powdered with sterile starch or lycopodium. The glove should then be picked up with sterile gauze and adjusted, beginning with the fingers, and, by means of gauze and forceps, applied to the fingers and hand.

Dr. DAWBARN thought there was no subject more deserving of discussion. He was one of the first to advocate the use of the glove, and, as Dr. Prince A. Morrow had stated, one case in eighteen operated upon was syphilitic; therefore the glove was a protection to the surgeon as well as to the patient. Perspiration made a great deal of trouble. Other things being equal, the surgeon whose hands did not perspire would be more successful than the one whose hands did perspire. He differed with the reader of the paper regarding the use of starch and lycopodium. Neither was soluble in the

uids of the body. There were six essentials for such a owder: (1) It must be impalpable; (2) it must be an ntiseptic; (3) it must be an astringent; (4) it must be on-irritating; (5) it must be soluble in the fluids of the ody; (6) it must be able to stand baking. He said that mixture of one-half dried aluminium sulfate and one-alf boric acid fulfilled these essentials. The potassium um would not do and it was necessary to have the dried lfate, which could be treated to 200 C. without altering condition as an impalpable powder. Gloves should dusted inside as well as on the outside.

Dr. ELSBERG said that any manipulation of the gloves ter sterilization gave chances for infection. At Mount nai Hospital the gloves were boiled and dried, then laid tween folds of a sterile towel, placed in a steam sterilizer, d hot air passed through. They were then dusted th sterilized powdered talc.

Dr. JOSEPH WEINER said that a punctured rubber glove uld be patched as a bicycle tire, after which they could subjected to dry heat, but not to moist heat. He vocated using very little powder and dipping the hands quently in bichloride solution, 1-500, when the gloves re on the hands.

A New Osteoplastic Amputation at the Ankle-joint.—. ALEXIS V. MOSCHCOWITZ read this paper and said that was not his intention to discuss those amputations in ich a portion of the os calcis or os astragalus could be erved. No one would deny that the Pirogoff amputon or its numerous modifications gave ultimate lts that were simply ideal, and, therefore, this operan should be the one of choice, provided that the os is was healthy and that sufficient integument could ad to cover the stump. He wished to speak of those es in which recourse must be had either to an amputon higher up on the leg, or in a few rarer instances the so-called Syme's amputation. He believed he had covered a method which, while preserving all the good alities of the Syme's method, excluded all its drawcks and disadvantages. So far as function was conned, he was convinced that the stump formed acding to this method must be *eo ipso* bad because the tal extremity of the stump was formed by bone sawn nsversely across. He believed the *sine quâ non* and ndamental principle of all amputation stumps to be t the distal extremity be covered either by normal tilage as in an exarticulation; or if the sawn surface covered or sealed by normal bone, covered by normal riosteum taken either from the bone amputated or m an adjoining bone. He then discussed the poor alities of the Syme's stump and brought up the ques-n how to amputate the foot at the ankle-joint and yet ve nowhere the sawn surface of any bone. This ques-n he solved as follows: The cutaneous incision was ade in such a manner and such place that he could tain ample healthy skin for covering the stump. If e had the choice it was preferable to carry the incision such a manner that the resulting cicatrix would not me to lie directly on the end of the stump, and of these referably anteriorly, because then the integument cover-g the stump would be formed of the thick heavy skin rming the heal. On no account should the length of the mp be sacrificed for the heal-flap. Exarticulation of e foot at the ankle-joint should follow, thus exposing e two malleoli and the contiguous portion of the tibia overed by its cartilage. An irregular octohedra-shaped iece of bone was now sawn out of the fibula in the folowing manner: The saw entered the fibula on the inner ide, approximately on the level of the cartilage covering he tibia, and was carried obliquely upward and outward bout 1½ cm. to within 1 or 2 mm. of the external surace of the fibula; the saw was then withdrawn and made o enter the external surface of the fibula also at the level f the cartilage covering the tibia, and was then carried ainly upward, but with a slight deviation inward, until it met the end of the first sawcut, thereby preparing a small osteoperiosteal flap from the outer side of the fibula, which could be readily fractured and deflected temporarily outward. The portion of bone removed had the shape of an irregular octohedron, one apex being at the tip of the malleolus, the other at the junction of the sawn surfaces, while the two lateral borders were on the external and internal surfaces of the fibula, on a level with the cartilages covering the tibia. The two sawn surfaces were then approximated and fastened by catgut sutures, which passed through the periosteum covering the parts. As well known, the internal malleolus was shorter and thicker and, therefore, it was necessary to have the saw enter the inferior surface of the malleolus about 2 mm. from its internal surface, and was carried in an upward direction to the level of the cartilage covering the tibia. This formed a small osteoperiosteal flap from the inner surface of the malleolus which was temporarily deflected inward. The remaining portion of the malleolus was now removed with a saw, also on a level with the cartilaginous surface. The two sawn surfaces were now approximated and held in place by means of catgut sutures, which passed through the periosteum covering the parts. If this stump be properly made he said that it would be divisible into three surfaces, viz., a small inner one, and a smaller outer one, covered by normal bone and periosteum, and a larger central one covered by normal cartilage, and all in all there would be found all the requirements present for the formation of a perfect end-bearing stump.

Dr. DAWBARN differed with the assertion that it was impossible to give an end-bearing stump by periosteal flaps. In the Syme's operation shortening the main nerve did away with discomfort.

Dr. GALLANT suggested that the articular surfaces might have been large enough so that it could have been turned out.

Dr. MOSCHCOWITZ replied that the cartilage was not in such a condition as would have enabled him to turn it out.

A New Hemorrhoidal Clamp.—Dr. MARTIN W. WARE presented this instrument, which possessed the advantage of having an ingenious attachment by which the operator could release it with the finger of the hand holding the clamp or with the other hand without the aid of an assistant. It was the consensus of opinion that the clamp was superior to any now in use.

Report of a Case of Adenocarcinoma of the Appendix with Presentation of Microscopic Specimen.—Dr. JOSEPH WEINER reported the case of a patient, thirty-five years old. As a child he had had inflammation of the bowels. Some ten years ago he had nervous prostration and later indigestion and much nausea for from five to eight months. He was seized while at business with severe pain in the right iliac fossa and by evening of the same day his sufferings were intense. He was taken to the hospital and operated upon. There were numerous adhesions low down. The appendix was very small and the base of it was almost obliterated. Near the ileocæcal valve there was a small tumor which proved to be carcinomatous. It was a typical adenocarcinoma.

Specimen of Carcinoma of the Larynx.—Dr. JOHN F. ERDMANN presented this specimen, which he had removed from a patient thirty-five or thirty-seven years old who had given a history of syphilis. He had also removed the epiglottis.

Rectal Incontinence.—Make a semicircular incision at one side of the anus, cut the sphincter muscle and freshen the edges or ends of the torn sphincter by taking a V-shaped piece out of the angle and suture the parts together. Then the flap is replaced and sutured and an aseptic dressing and T-bandage applied. Chetwood's operation is also valuable.—PENNINGTON, in *Medical Standard*.

THE PRACTIONERS' SOCIETY OF NEW YORK.

One Hundred and Eighty-Sixth Regular Meeting,

Held on February 5, 1904.

DR. CHARLES STEDMAN BULL, PRESIDENT, IN THE CHAIR.

The Local and Systemic Relations of Sarcoma.—Dr. GEORGE F. SHRADY read this paper. (See page 521.)

Dr. GEORGE L. PEABODY said he had always supposed that of all the types of sarcomata, the spindle-celled was the least malignant, and was therefore less apt to recur than either the round or giant-celled variety.

Dr. Shrady said that in his experience, the subperiosteal spindle-celled sarcoma had proved exceedingly malignant. The recovery in his case had therefore been a great surprise. The patient was still in excellent health and showed no evidences of a recurrence. So far as he could learn, it was the only case on record in which recovery had followed that particular operation, *i.e.* amputation of the thigh, and there were only six cases on record of recovery after amputation of the hip. Dr. Shrady said the possibility had occurred to him that in those six cases recovery might also have taken place if the less serious operation of amputation of the thigh had been done instead.

In reply to a question as to the value of Coley's serum in the treatment of sarcoma, Dr. Shrady said he had seen two or three cases in which the use of the toxins had caused a remarkable shrinkage in the size of the growths. In one case of osteosarcoma of the ilium the growth entirely disappeared under the toxin treatment, but there was a recurrence within six months. The injection of the toxins was usually followed by severe constitutional symptoms. The treatment was applicable only to inoperable cases.

Dr. JOHN WINTERS BRANNAN said that while metastases were apt to occur after any operation for sarcoma, he thought it was reasonable to infer that in dealing with a sarcoma involving an extremity, the danger of a recurrence by continuity was lessened by removal of the entire member. The same principle was followed in the radical operation for cancer of the breast. In sarcoma of the thigh, anything less than a hip-joint amputation would not remove the danger of extension through the bone, and the speaker said he understood that that was the way by which a recurrence by continuity usually traveled.

Dr. Shrady said that in all the cases he had studied, the recurrence could be traced to invasion of the soft structures rather than the bony tissues. A point in favor of amputation through the thigh was that the operation itself was much less fatal than a hip-joint amputation, and many patients would consent to the former operation while they would refuse the latter. Of course, no surgeon would think of enucleating a malignant tumor of the thigh if the growth was ultimately incorporated with the bone. In all such cases, some form of amputation was necessary, and the question to decide was, how much of the limb must be sacrificed.

Dr. Peabody said it had always seemed to him that in cases in which the medullary cavity was invaded the prognosis was rendered more serious.

Dr. Shrady said that it had been his aim to prove the very opposite of this condition, and that dissemination took place mainly, if not entirely, by invasion of the soft tissues outside the bone.

A Case of Recurrent Intraabdominal Abscess Accompanied by Unusual Lesions in the Mouth.—Dr. ANDREW H. SMITH reported this case, which he said was unique in his experience. The history of the case dated back fully twenty years. The patient, at that time a young woman, was seized rather suddenly with an attack of pain in the region of the gall-bladder. The abdominal muscles were extremely tense, so that palpation was unsatisfactory, but there was evidently a sense of resistance in that region, although no well-defined tumor could be made out. There was great tenderness on deep pressure. The attack was accompanied by a rise in temperature; there was no jaundice. After a few days there was a discharge of pus and blood through the bowels, and subsequently the symptoms disappeared. There had evidently been an abscess in the region of the gall-bladder, but apparently not connected with the liver, and this had ruptured, probably into the transverse colon. Coincident with these abdominal symptoms, a peculiar lesion would appear in the mouth. The little ridges on the roof of the mouth, just above the base of the incisor teeth, became swollen and painful, and gave the patient much distress. Although there was apparently no suppuration connected with the teeth, the presence of pus was suspected, but upon making an incision nothing but blood was obtained. With the subsidence of the intraabdominal symptoms, the oral lesions also disappeared. During the past twenty years the patient had had at least a dozen attacks, practically similar to the one described, although in some of them the intra-abdominal condition did not reach the point of suppuration. The last attack occurred only a few weeks ago after a period of immunity of over six years. In all these attacks the oral lesion was a very distressing feature. In reply to a question, Dr. Smith said he had never urged operation for exploratory purposes, nor did he think the patient would consent to it, as she had always made a satisfactory recovery from the attacks and enjoyed good health in the interim. He thought the original lesion in the abdomen was an abscess external to the transverse colon, and after it had ruptured, more or less of a deposit remained, which had been the cause and seat of these repeated recurrences. He had no explanation to offer for the lesion in the mouth. In appearance it resembled the condition often seen in horses, and known to veterinarians under the name of *lampas*.

Dr. PEABODY recalled a case of deep-seated suppuration below the liver in which the abscess finally reached the surface. Its contents were evacuated, and the cavity was then irrigated with a watery solution of iodin. after one of these irrigations the patient had a severe fit of coughing, with some expectoration, which left a deep blue stain upon a starched handkerchief. On another occasion the irrigating fluid failed to return and the patient shortly afterward had a watery evacuation from the bowels which stained the bed-clothing blue. Sinuses from the abscess cavity had evidently burrowed through the diaphragm into the lung, and also communicated with the bowels. The patient eventually died of inanition, and the necropsy revealed a perinephric abscess which had burrowed in every direction. This case, Dr. Peabody said, was seen long before the days of asepsis, when laparotomy was not resorted to as frequently as now. At present surgical treatment should be recommended, in his judgment, in all such cases.

A Case of Profound Malarial Coma.—GEORGE L. PEABODY reported this case. The patient was a well-nourished man, thirty-nine years old, who was brought into the New York Hospital during the early morning of November 25, 1903, in a condition of coma which was so profound that it was impossible to rouse him to consciousness. There was no paralysis of any of the extremities. The only history obtainable was that he had come from a steamer which had arrived that morning from Panama; that he had had some form of fever in Central America and at sea, and had become delirious and then comatose during the voyage to this city. There was no history nor indications of an injury to the head or elsewhere; the urine was negative; there was no œdema; there was no evident arterial degeneration; there was no rigidity of neck. An examination of the blood showed no malarial parasites, but there was a peculiar cachexia which Dr. Peabody said reminded him of the cases of profound malarial poisoning that he had

served during the building of the Panama Railroad. s temperature was 97° on admission. It rose gradually 102° on next day. Acting on the theory that the se was one of malarial coma, quinine was administered r *rectum* at 5 P.M., and a subsequent blood examina- n revealed two crescents. Two days later, after pro- ged search one ring-form was found. These were e only organisms found during the man's stay in e hospital. Muriate of quinine, in combination with a, was then given hypodermically, 20 grains one hour er the rectal dose, 10 grains at 9.30 P.M., and 10 grains e following morning, and directions were left not to e any more until the third day. On the second day e patient's pulse had become very weak, necessitating ive stimulation. He was given whiskey *per rectum* d digitalis subcutaneously, and to these measures he ponded very promptly. He became conscious about ty hours after the administration of the first dose of inine, and on the following morning he was perfectly tional, and was able to sit up in bed and take nourish- nt by the mouth. Twenty-four hours later he began behave queerly, continually insisting on getting out bed, so that it became necessary to restrain him. He ally became so troublesome to the other patients that was transferred to the Pavilion for the Insane at llevue. After two or three days there, he became rfectly rational, and remained so until he was dis- arged from that hospital, entirely well, several days er.

Dr. BEVERLEY ROBINSON said that the case reported Dr. Peabody was a good illustration of the fact that larial parasites could not always be demonstrated in e blood even in cases of profound malarial poisoning. Dr. Peabody's case only a single malarial organism d been found, and the examination of the blood made ior to the use of quinine had proved negative. The eaker said he had often met with similar cases of un- ubted malaria, in which repeated blood examinations d proved negative. In certain cases of malaria, par- ularly those of a chronic nature, he had found War- rg's tincture very efficacious after a very thorough rse of treatment with quinine had failed to relieve e symptoms. The older writers, among them the te Dr. Loomis, spoke very highly of Warburg's tinc- re in chronic malarial poisoning, while the more recent xtbooks rarely mentioned it.

Dr. Peabody said he had seen cases of undoubted alarial poisoning in which the parasites could not be und in the blood after repeated and careful investigation, t such instances, he thought, were rare. In cases in hich the clinical diagnosis was satisfactory, it was his stom to delay treatment for twenty-four hours, and if that time the organisms had not been found, the inine was given without the bacteriological confirma- ry evidence. In the case he reported, Dr. Peabody id, it was probable that the man had received a certain mount of quinine before he arrived in New York; per- aps not enough to benefit him, but enough to interfere ith the number of the organisms. The spleen was ot palpable, nor was the liver.

Dr. BRANNAN said that he saw numerous cases of severe alarial poisoning after the Spanish-American war, nd many of these responded to Warburg's tincture fter quinine had failed. Since then the suggestion has been made by some authority to withhold the quinine until the temperature had begun to decline; to begin then and give five grains every half hour until twenty grains were given, and then stop, the same course of treatment to be repeated if another paroxysm occurred. The writer held that the spores were most vulnerable during the decline of an attack. Dr. Brannan said he could recall several cases in which prompt relief was ob- tained by this method, and there were no further parox- ysms.

Dr. Peabody, in reply to a question of whether there were cases of malaria that would not yield to quinine, properly administered, said that now and again he thought he had seen such cases. They were certainly very rare, however, and in those particular cases, perhaps, the drug has not been properly given. Some cases that did not yield to quinine alone were relieved by Warburg's tincture or a combination of quinine and arsenic.

Dr. ROBINSON said the late Dr. Loomis favored as an initial dose ten grains of quinine and ten grains of blue mass.

Dr. SHRADY said the late Dr. Clark prescribed quinine, in combination with capsicum and opium.

NEW YORK STATE MEDICAL ASSOCIATION.

Special Meeting, Held March 21, 1904.

THE PRESIDENT, DR. WILLIAM H. THORNTON OF BUFFALO, IN THE CHAIR.

IN accordance with the request of twenty-five members of the New York State Medical Association, a special meeting of this association was held at the New York Academy of Medicine, New York City. The purpose of this meeting was to hear the report of the Committee on Conference of the New York State Medical Association, Dr. E. Eliot Harris, chairman, looking toward the union of the New York State Medical Association and the Medical Society of the State of New York.

After this report had been presented by Dr. Harris, the following resolution was offered:

"*Resolved*, That the report of the Joint Committee of Conference be accepted, and that the proposed agreement for the consolidation of the Medical Society of the State of New York *and* the New York State Medical Association be and the same is hereby approved, and the president of the association is hereby authorized and directed to execute the same in the name and behalf of the association, and the secretary is hereby authorized and directed to affix the corporate seal thereto, and be it further

"*Resolved*, That the committee of the association heretofore appointed for the purpose of bringing about the consolidation, namely, Dr E. Eliot Harris, Dr. Julius C. Bierwirth, Dr. Alexander Lambert, Dr. Parker Syms, and Dr. Wisner R. Townsend, be and they are hereby continued as such committee, with full power and authority to do whatever may be necessary to carry the agreement into effect."

This resolution was seconded, and before further action was taken Dr. E. D. Ferguson of Troy requested a few minutes to address the association before acting upon the resolution. He said he was not there to oppose the action because he knew that, according to the run of human events, it was useless for him to attempt to negative the recommendation of the committee. He was present to express sentiments of his own and those of the gentlemen from up country, members of the association. He did not believe they had been justly dealt with. He referred to the long struggle the association had in coming to this point of having a union. He said that at first they were sneered at and laughed at. The American Medical Association allowed the old members to come to their meetings to read papers and that was all they wanted. He said that when the line was drawn at the Denver meeting and the declaration made that to become members of the American Medical Association men *must be* in proper affiliation with the State Medical Association, the necessity of getting into the State Medical Association in some form or fashion was pressed upon them. The door was then opened and they became members of the State Medical Association. Then began the wiggling process. He said it was the Medical Society of the State of New York that came to the New York State Medical Association and asked for union, and this occurred over two years ago. He said the New York State Medical Association did not ask for it, although willingness was expressed that the union should be effected. At the Saratoga meeting, willingness for union was expressed. When the committee was appointed

the request was made not to place upon it the old members but to have new blood on that committee. He said that there was not one old "war-horse" upon it. A battle was engaged in at the New Orleans meeting and an amendment made to the Code, which he did not believe was needed. Now he asked if the union was a just and equitable one. After referring to the terms of the union and the proposed plan for reorganization, he said it was not the original plan at all of the New York State Medical Association. He spoke of the danger of control by cliques and said they had yielded everything, including name and all else and had been simply swallowed. This was not union but engulfment. From the bottom of his heart he said he felt the injustice and the wrongfulness of it, because he believed the association was bereft of everything it stood for. He closed his remarks by saying: "I have no doubt that this resolution will be passed. I am not going to say good-by to the State Association. I go." Dr. Ferguson then left the building before action was taken on the resolution.

The PRESIDENT then put the question and it was passed without a dissenting voice.

Dr. JOSEPH D. BRYANT then offered the following:

"*Resolved*, That the County Association in affiliation with the State Association be requested to ratify the action of the State Association." This was seconded and carried.

After the president had expressed thanks to the County Association for its courtesy in giving the State Association the time for its meeting, the meeting adjourned.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, Held March 21, 1904.

DR. ALEXANDER LAMBERT, CHAIRMAN.

Reorganization of the Medical Department of the United States Army.—Dr. NATHAN S. JARVIS asked for the association's coöperation in the successful passage of this bill which had for its principle object the avoidance of the unpreparedness which had characterized not only our own medical corps but that of Great Britain. In the recent war with Spain there was needless hardships for the soldiers on this account. He said that the United States Navy with its 41,000 men had 100 per cent. more medical officers than the United States Army. In the navy promotion occurred in three years while in the army it required five years. To become a lieutenant commander in the navy required but ten years; to be promoted to its equivalent in the army required from twenty to twenty-five years. The recent war with Spain had demonstrated the necessity of an increase in the medical corps of the United States Army, and because much avoidable danger and hardships had been given the troops by reason of the lack of experience and lack of training in military sanitation, etc., he asked the support of the Fellows.

The Elsberg Bill.—Dr. E. ELIOT HARRIS offered a resolution which was adopted supporting the Elsberg bill which was now before the Assembly; this bill provided for the abolishment of coroners in New York City.

Resolutions upon the Death of the Secretary.—It was moved and seconded that the chairman appoint a committee of three to draw up proper resolutions regarding the death of the late secretary, Dr. Ogden C. Ludlow.

A New Instrument.—Dr. SAMUEL T. RUCKER of Chattanooga, Tenn., presented an instrument for use in packing the uretha in cases of gonorrhœa, gleet, or stricture. The instrument was made of glass, with a flange for the fingers, and a plunger. He said it was really not for packing but for applying dressings to the urethra. The dressings could be left in from five to eight hours without discomfort. The doctor also showed a glass sound which he considered superior to those in ordinary use because of its smoothness, cleanliness, and ease of entry.

Officers Elected.—*President*, Dr. Francis J. Quinlan; *First Vice-President*, Dr. Henry A. Dodin; *Second Vice-President*, Dr. S. Busby Allen; *Secretary*, Dr. Wm. R. Stone; *Corresponding Secretary*, Dr. John J. Nutt; *Treasurer*, Dr. Charles E. Denison; *Executive Committee* for three years, Dr. Alexander Lambert; for two years, Dr. [illegible] W. Loughran.

CHICAGO MEDICAL SOCIETY.

At a meeting of this society, held March 2, 1904, the evening was devoted to the presentation of cases illustrating the various phases of "Syphilis." Dr. Hugh T. Patrick presented a woman, forty-one years of age, whose trouble dated back to 1899. He saw her in 1901 for the first time. She suffered from dizziness, failure of vision, intense headaches, considerable mental and physical lethargy tude. Following this she developed double vision which lasted for a few months. Acuity of vision diminished rapidly, according to the statement of the patient. After having had this trouble for some time, she sustained a fall and was unconscious for a short time. When she regained consciousness she vomited. A month later she had another fall, and was also unconscious for a short time. During this time the severe headaches continued. After several months of these headaches, mental lethargy, double vision, and two unconscious attacks, she was removed to St. Luke's Hospital, and on the day following her arrival became unconscious, and remained so for twenty-four hours. She vomited just before she became unconscious. When she regained consciousness, everything looked blurred, and the left side was paralyzed. The arm became weak first, then the leg, and later the face became involved. With the left hemiplegia there was marked sensory disturbance; marked anæsthesia, which continued for a considerable time. Two years after the attack, when patient had regained very good use of the left side, there was still considerable subjective trouble on that side, but very little objective. Patient uses the left hand for practical purposes, but it is not as dexterous as it was, and feels queer. She has complete homonymous hemianopia. The visual field is normal on one side, but gone on the other. As the result of her trouble, patient has permanent hemianopia, although she has nearly recovered from her left hemiplegia. Patient is absolutely ignorant of any specific infection. Dr. Patrick presented another case, a woman, twenty-one years of age, whose mother is at present suffering from tabes, with optic atrophy. The oldest child, a son, died about two years ago from general paresis. The next child, also a son, is at present suffering from tabes, with optic atrophy. Patient is the third and only remaining child, who, as an infant had snuffles, and later developed mucous excrescences. Two and a half years ago she had a typical interstitial keratitis, but up to three years ago, aside from the trivial ailments of childhood, she was well. One day, while getting on the step, she had a sort of stroke without loss of consciousness; became weak on one side, more especially in the face. The next morning she had another stroke which involved all of the right side. This attack was transient. A month later she had another attack of right hemiparesis, which was a little more severe, and three months later a fourth attack, which was very severe, which left her completely hemiplegic on the right side, with aphasia. First the face, then the arm and leg became involved. A year and a half ago, patient developed typical Jacksonian fits. These fits started with twitching and drawing in of the right side of the face, which extended to the arm, then to the leg, after which she had a general epileptic attack. Sometimes the spasm does not go so far. The face and arm may be convulsed, without loss of consciousness. Sometimes she has a severe attack which terminates in a general convulsion. Attention was called to the defective teeth of the patient. She also has a disseminated choroiditis. Patient showed unmistakable signs of hereditary syphilis, and Dr. Patrick said the question arose whether the two boys inherited syphilis or had

communicated to them as children. Either case was ossible; but the family showed the relation between ecific disease, tabes, and general paresis.

Dr. L. Blake Baldwin showed a Chinaman with syphilis, e had treated eleven cases of this disease in Chinamen. e brought the case for diagnosis. As it was difficult to t a history of such cases, he ventured to say that 90 per nt. of the cases of Chinamen who consulted physicians d this disease. With this thought in mind he had given l of them iodide of potassium with good results in most ses. When these patients presented themselves with ial paralysis, paralysis of the arm and leg, with large erations on the leg, it was wise to give them iodide of tassium. The patient denied any initial lesion. Dr. ldwin showed another case, a man with a diagnosis of philis. The patient had a chancre eighteen years ago. now had syphilitic iritis, but had improved consider- y under the use of iodo-neucleoids. He mentioned a e similar to this that had made a perfect recovery. out five years ago this patient had a paralytic stroke the left side, so that he was unable to move his fingers, the paralysis lasted only half an hour. He also showed e cases of syphilitic lesions of the mouth. One patient a chancre fourteen years ago, but no eruption on the y. Since that time patient had had two soft chancres t a year ago, which were cauterized by a physician. fauces were congested; there was a gumma situated the posterior wall of the pharynx. He recalled two s in which there were secondary eruptions and mucous ches. The men acknowledged having had syphilis e twelve or fourteen years before. Dr. Frederick ge showed a boy, twelve years of age, who had heredi- syphilis. Patient had an active proliferating gumma e nose, springing from the septum on both sides, filling anterior meatus and occluding both nostrils. He had complete erosion of the uvula. The second case was a g man who had large syphilitic eschars on the soft hard palates. The uvula was almost obliterated from ilitic erosions. In this case the infection occurred teen years ago, while the erosions caused the scars three s ago. The third case was a man who had paralysis e left vocal cord from the pressure of an aneurysm of arch of the aorta on the recurrent laryngeal nerve. Geo. F. Suker showed a boy who had a typical syph- e head. He had the tripod of Hutchinson: interstitial titis, otitis media, and saddle nose. Patient had ilitic rhinitis, bilateral dacryocystitis; stenosis of the ymal duct. Patellar tendon reflex was not lost. ent had what is called the Darier tooth; atrophy of the er jaw and of the hard palate. He had had these tions since the second week of birth. Attention was d to the typical Hutchinson's teeth. The boy was a cal example of hereditary syphilis. Dr. E. A. Fisch- exhibited a patient who gave a history of having had a ary lesion some twelve years ago, the nature of ch was not definitely known. Patient said he did not e secondary lesions, but did have mucous patches, was free from other manifestations of the disease for ve years. Patient had been married five years, and healthy children. About fourteen months ago pur- ic spots began to appear on the lower extremities. ee months ago tubercles began to appear on the side the nose, which were circinate in form, gradually en- ed, and finally ulcerated. Patient was put on the de treatment and given mercurial inunctions. Soon whole leg was covered with purpura, but the spots e closer together, particularly on the surface where the ment was rubbed in. The question arose in the thor's mind as to whether he was justified in calling the e purpuric syphilis, or was the purpura due to the toxic ect of the treatment? Against the latter, it should be d that the patient had purpura twelve weeks ago with- t treatment. The second case was a girl, fifteen years age, who presented a typical tertiary, ulcerating syph- ilide on the leg. She also presented syphilitic scars of the type represented by atrophy and pigmentation. The history was entirely negative. The disease was of two years' duration. If she had acquired syphilis, the primary infection must have taken place when she was twelve or thirteen. There were a number of scars on the leg and a general adenopathy. Dr. Fischkin detailed two other cases of syphilis. Dr. Geo. F. Suker showed two cases of syphilitic iritis. In one the eye was very painful, while in the other the condition was unattended with pain. One had a small corneal ulcer. This patient admitted having had syphilitic infection about a year ago, but now had the secondary manifestations of the disease, with marked adhesions of the iris, and excessive proliferation of the pigmentary layer of the posterior surface of the iris, with a large portion of the anterior surface of the capsule of the lens being involved. There was great reduction in sight, with pupillary adhesions. The ulcer was situated toward the nasal side of the cornea. Dr. David Lieberthal showed a case of secondary syphilis, and discussed the differential diagnosis between syphilis and lupus vulgaris. Dr. William L. Baum showed a patient on account of the anomalous action of some scar tissue of syphilitic origin. The man had been under treatment a number of years ago at his clinic. At that time he presented himself with a history of specific infection followed by ulcerations and keloid-like growths. These were hard and firm and projected beyond the surrounding skin. The symptoms for which he was previously treated had disappeared; but some four months ago the patient returned complaining of nocturnal pains and of infection. He, therefore, put him on iodo-nucleoids with astonishing results, in that the keloidal thickening had almost entirely disappeared. A feature of unusual interest was that repigmentation had started in the scar tissue. This was generally denied. He was not prepared to offer any explanation for it, but it was contrary to our ideas of pathology and the physiological relations of this process. Dr. Hugh T. Patrick, after examining Dr. Baldwin's case of the Chinaman, said it was one of thrombosis of the Sylvian artery, with right hemiplegia and aphasia. Patient had exaggerated reflexes and the typical Babinski sign.

Philadelphia Pediatric Society.

At a stated meeting, held March 8, Dr. Wm. Drein exhibited "A Patient with Enlargement of the Liver and Spleen, Probably Syphilitic." The case occurred in an undersized boy, fourteen and a half years old, with a history of syphilis in the father and of evidences of the same disease in other children. In the patient exhibited there had also been cutaneous manifestations, keratitis, sinuses, bone-deformity, and other indications of syphilis, in addition to the enlargement of the liver and the spleen. Dr. D. J. Milton Miller read the notes of "A Patient with Pulmonary Hypertrophic Osteoarthropathy." The case occurred in a child with spondylitis and deformity of the thorax, together with symptoms and physical signs of disease of the lungs, but without obvious disorder of the circulation. The extremities of the toes and the fingers were greatly enlarged, and skiagrams disclosed hyperplasia of the terminal phalanges. Dr. L. J. Hammond exhibited "A Patient with Hypospadia, Inguinal and Umbilical Herniæ." The case occurred in an infant a few months old, the defect in the urethra being partly balanal and partly penile, the prepuce forming a hood suggestive of the clitoris. The left testicle was in place in the scrotum, while on the right side the inguinal canal was enlarged and patulous, permitting the descent of the bowel, to which the right testicle was adherent, presumably as a result of an inflammatory process during intrauterine existence. The presence and the condition of the right testicle precluded the employment of any supporting mechanism for the retention of the bowel in the intestine and indicated surgical interven-

tion, at least for the separation of the testicle from the intestine, after which the employment of some retaining mechanism might prove feasible. Drs. D. J. Milton Miller and J. C. Gittings reported "A Case of Pyopericardium Complicating Ileocolitis in an Infant of Four and a Half Months." The patient was a foundling, presenting cough and diarrhœa, with symptoms of bronchitis and ileocolitis. Death took place in the course of twelve days, the temperature meanwhile pursuing an irregularly elevated course. On post-mortem examination there were found, in addition to the inflammatory condition of the intestines, an accumulation of pus in the pericardial cavity and the structural alterations of in terstitial pneumonia. Dr. H. K. Hill read a paper entitled "A Case of Intussusception; Operation; Recovery." The patient was a child that had suffered a good deal from gastrointestinal disorders, and presented vomiting and diarrhœa, together with prolapse of a portion of bowel from the anus. Operation was undertaken without delay, the abdomen being opened and the invagination reduced. The patient made an excellent recovery without complication. The case illustrated the good results of prompt surgical intervention.

Cincinnati Hospital Staff Meeting.

The members of the Cincinnati Hospital Laboratory staff demonstrated to the clinical staff of the hospital, on March 10, matters of interest which had come up in their services during the past month. Dr. J. E. Greiwe showed two specimens of tuberculous pericarditis, One case showed great thickening of the parietal and visceral pericardium with very little fluid and no blood in the sac, while the second case showed a tremendous dilatation of the pericardial sac with blood-stained fluid, so that it extended laterally to the ribs on the left side. Microscopically both cases showed tuberculous structure with giant cells in large numbers, while the second showed many newly-formed blood-vessels in the thickened pericardium. Dr. J. W. Rowe showed the kidneys of a case of septicæmia in which just beneath the capsule small nodules could be seen which on microscopical section, were shown to be areas of small round-cell infiltration. Dr. Frank Fee showed gross and microscopical sections of a case of elephantiasis of the skin of the legs and abdomen, from a colored woman weighing 350 pounds. Dr. Wm. Muhlberg demonstrated the new precipitation test for human blood by means of serum obtained from an immunized rat. He also demonstrated some stained specimens of trypanosomes from the rat. Dr. Carl Hiller demonstrated a bacillus which he had isolated from a thrombus from a posttyphoid gangrene of the leg. He had not yet been able to find any description of a bacillus with similar properties. It was a short, thick non-motile bacillus with a tenacious capsule. It formed spores after a short time; no flagella could be formed. Gram's stain was positive. Its growth was luxuriant on blood-serum with a heavy deposit of a salmon-colored pigment. On agar the growth was not so marked and less pigment was formed. It grew also in gelatin and bouillon—in the latter without pigment. On potato it formed some pigment. It was facultative anaerobic. Injections were made in a guinea-pig which had as yet been negative.

In Fracture of the Skull, whether linear or otherwise, trephining should be performed as soon as possible on account of the danger from sepsis. Thorough irrigation with normal saline solution, continued for ten to twenty minutes, and when any spiculæ of bone are carried into the brain, this irrigation should be carried to the very bottom of the wound. There should also be drainage by either catgut gauze or tube, but it can be dispensed with if no pus is found at the end of the third day. The hemorrhage can be arrested by hot normal saline solution.—Eve, in *Southern Practitioner*.

JOSEPH O'DWYER, M.D.

METHODS OF WORK ON INTUBATION; THE MEASURE OF HIS SUCCESS; THE INTEREST OF BOTH TO YOUNG GRADUATES.*

BY W. P. NORTHRUP, M.D.,
NEW YORK.

President, and Members of the J. C. Wilson Society:

As I understand it, I am invited to address young duates and under-graduates of medicine, on a ject akin to medicine, yet not strictly and usively medical. I was allowed to select my ject, and yet a subject was suggested by Dr. lson. His selection shows at once an appreciaon of the qualities of the person to be named, d my attitude and feeling toward the person. It largely the delicate tact of Dr. Wilson and his preciation of the man, the subject of this paper, ch accounts for my presence here this evening.

I am invited to speak to you on the subject—eph O'Dwyer, not his achievements, for the rld knows them; not the invention which has blished his name in every language. I am ited as one who knew O'Dwyer intimately for teen years, to talk to you of the man. I am ed to tell you what there was in his life, his aracter and his work, which may be of interest d improvement to young men, just "outfitted," they said in Klondike days, for a long career; tell the ambitious, who admire achievements, w success may be attained; to show the humble inner who feels handicapped, because he has not ily and wealth to aid his first efforts and feels self hard favored in the lack, what can be mplished where there is energy, intelligence, d devotion to a cause.

Let us inquire what was O'Dwyer's success? s it worth while? We point to intubation—operation supplanting tracheotomy, an operation ning ground every year and never losing. This ration bears undeniably and without dispute Dwyer's name, and his alone. No one else really ims priority, no one claims to have added an ential improvement. Intubation stands as his disputed monument. Is that success? Is it cess to have added a new operation to medical d surgical procedures, to have placed a name ere it will never fade? I hear the ambitious dent acclaim it to be such.

Did fame constitute all his success? Did intubaon do anything for him, beyond immortalizing his me? The ambitious young man will wish to ow whether it brought him fortune. Money is gely in the mind of the ambitious. My answer "no." It did *not* bring him much money. To nother, differently constituted, it might have me so. He, for a few short years, made some oney out of his invention, but soon others could the operation as well as he. Some were so loud in praise of intubation, advocated it so strongly, proclaimed their results so widely, that I fancy several intubationists made more profit from the operation than did Dr. O'Dwyer. Did he receive any other return? Did it bring him position and consultation? Honor and high esteem and some consultation it brought him. To a more aggressive man it would have brought more, to a less modest, retiring man it would have been a stepping-stone to all manner of success.

He was offered opportunities to teach. He gave one lecture at the Bellevue Hospital Medical School and never gave another. His name stood on the list and he was urged to continue but declined. Great diffidence and physical languor, will explain much of it, but a more modest man never lived.

His wife was most diligent in learning every word said or written on intubation. Very little could she get from her husband. At the time of his ovation in Washington, when intubation had its first large audience, I hurried over to the hotel where she was and sent a note to her room. I am quite sure he would never have told her of the figure he personally had cut in that meeting. He was diffident, shrinking. His moderation of speech was also characteristic. I recall an occasion when we were disappointed in a well-recommended house physician coming from a distance. To say we were disappointed is toning down the language for a mixed audience. I could find plenty of words singly and in combination which would give a fair notion of my feelings toward this self-same young man. Not so O'Dwyer. One day, after an accumulation of aggravating incidents, I saw the light in O'Dwyer's eye. It's got to come now, I thought. It came—one word—not at all to my satisfaction, totally inadequate, but O'Dwyer's strongest in a fifteen years' acquaintance—it was "whelp."

How did intubation affect his general professional work? As it became a success he found it necessary to let go some of his general practice. Few know that O'Dwyer had attended three thousand confinements. Intubation was incompatible with obstetrical work; that must go—in part at least. In order not to be in competition with his neighboring practitioners, he felt it his duty to increase his charges per visit. That cut off more work. So long as diphtheria consultations were frequent and intubation consultations came in rapidly, there was compensation. Then came antitoxin. In the success of that O'Dwyer read, less need of intubation and less consultations in diphtheria. He had reduced his general practice by the temporary run of consultation and intubation. Antitoxin came to take them both away. He saw this early and clearly.

I recall the promising early results of calomel inhalations for croup—laryngeal diphtheria. It was thought to reduce the mortality from 75 to 40 per cent. "It is good, it will do till we get something better"—words almost prophetic, for antitoxin arrived on earth within twelve months. One of the first arguments I felt willing to accept, favorable

*Read before the J. C Wilson Medical Society, Philadelphia, February 19, 1904.

to antitoxin, was O'Dwyer's. "Yes," he said, referring to the deaths with his tubes in the larynx, "I used to put tubes in, now I am taking them out."

I have spoken of the fame that this man reaped from one of the most valuable contributions to medicine of my time—especially to pediatric medicine. Let me tell you what he reaped from it incidentally. He reaped an anxiety and worry which contributed to his death. All worried him. Another could have thrown it off and slept, but not he. He was sensitive. Every accident hurt him, every unfavorable criticism disturbed him. Naturally a poor sleeper, he lost more and more the ability to sleep. Behold the triumphs of the inventor, behold the slow death of the man. He died at fifty-seven, of arteries older than his years. Intubation first made and then killed O'Dwyer.

It should be mentioned in this connection, that in the early days of greatest triumph, six months after the ovation given him in Washington, he lost his wife. She had been quite the ideal companion for him, the very complement of his disposition. He mourned her loss till his death. She left him lonely, sleepless, failing in health. His four children were all that young boys could be of comfort, but poor health in one worried him.

I have spoken of O'Dwyer's success. It was the success peculiar to genius. A good business man would have achieved higher position and money. We can recall how men have devised or have adapted new methods of procedure and traveled around the medical world exploiting them. I well remember how, at the King's Reception to the Medical Congress, in his palace, at Copenhagen, a characteristic American hustler, from my city, after hurriedly greeting an acquaintance, exclaimed (as though the advertising habit spoke of itself), "Come around to the clinic to-morrow and see me put on such and such an apparatus." O'Dwyer, in Berlin, when a pediatric dinner was given by Henoch, could not be found. I was commissioned to find him and fetch him—but could do neither. He simply shrank from the wear of notoriety and disappointed a dinner.

Now, gentlemen, members of the J. C. Wilson Society, you must indulge me a little in this reminiscence of my dead friend. You have asked me to tell you the story of a fifteen years' life as colleague. Dr. Wilson said it struck him that the life of O'Dwyer had in it something of profit to the student and beginner. I have spoken of my friend as he was. O'Dwyer died poor, but his life has left a heritage to his boys better than competence. Indeed, competence has come to them through his friends. Columbia College, in remembrance, did a unique thing in its history, created a scholarship—the Joseph O'Dwyer scholarship, to lapse when Joseph, Jr., had graduated. I must pass over private aids to furnish the education of the others. Suffice it to say that they have all been educated, and are absolutely better off than a moderate fortune would have made them. At this moment, the son and namesake has been presented with an office and overflow practice by a friend of the father. Dr. Joseph O'Dwyer, a graduate of the N. Y. Foundling Hospital, now practises medicine and intubation in New York City.

Their father's name has not one spot upon it. No one disputes his sole ownership of his invention. No one has added a single essential accepted improvement to its construction.

The instrument-maker who put upon the market the completed patterns of the tubes has presented to the Academy of Medicine a historic collection.

Two years ago I sent in my card to the leadi intubationist in Naples. I feared he might n know me, so I wrote one word on the card, "Intub tion." In half a minute the door opened and, t emotions of an Italian showing in his face, the gent man arrived, both hands extended, "And you w a friend of my friend." He cherished every let O'Dwyer had written him, had his photograph the wall, avowed that he loved him fervently. I few days of acquaintance I heard over and over h much he admired and loved O'Dwyer. No m lives who can come forward and say O'Dwyer an unmanly act, made (knowingly) an untrue, warranted or unkind statement.

It is a simple story, as you see, of a man not rounded with stimulating advantages, not aided family or wealth, gradually proving himself exceptional man. He was a marked man from time he graduated. He developed and grew bec it was in him individually. He studied and r nated. Not one of his associates did much of eit so far as I can see. He was one who thought his cases and his work. He did all kinds of and thought on all varieties. Many here would sider the class of work an intolerable bore. T thousand cases of obstetrics in poor surrounding not what one would call stimulating to thou Much of his time and strength went to church p It was in him to work out problems and think cases. He really *knew* more general medicine t most men.

This simple story must go on to state what is recorded in medical literature, that O'Dwyer h memory among his colleagues, of a purity of c acter, an uncompromising honesty and upright which is almost childlike. Literally his word given constituted an obligation which no circ stances could weaken. He might be ever so s on learning more facts, but he would do wha had promised.

Our story must say that he had no enemies.

Again I say—though he left no fortune to edu his boys, he left so many friends, bound to h with such imperishable bonds, that all of the b have had the best and are equipped for their work. I might almost assert that there are hundred men in Gotham, good for a sight draft the needs of a son of O'Dwyer. It is a nam touch men with.

The development of intubation: The e history of the forms of instruments has been wri by several and is available. Perhaps it will inte you more to hear what has not been written what a young man saw and knew of the develop of intubation.

In 1882 I began making autopsies in the un ground cell of an out-of-the-way corner of a ce of the Foundling Hospital. (We have better n Systematic autopsies were a new thing, from w all female hearts shrank. Because O'Dwyer wi it, Sister Superior, Sister Irene consented. often told me if she knew what a terrible ener was going to develop and how much we were going to do "downstairs" she would never h consented. She would, though, just the sa for she could never refuse O'Dwyer, and th was a twinkle in her eye when she tried to l sober.

Down in this skylighted cell (it is a concessio say skylighted, for it was scarcely lighted, snow-covered corrugated glass pointing skyw but level with the ground and in the angles of h buildings), down in this cold corner O'Dwyer c constantly with devices which he wished to thr into the larynx. The first of these instrume

t I ever saw was like a bivalve uterine speculum, ut an inch long. The main difference was, ides size, that they opened with a spring and a gutta-percha collar. The study of the collar the first that gave rise to discussion, which I remember. Dr. E. R. Chadbourne was the ing house physician, an ingenuous mechanic a great aid to building the first instruments. and Dr. O'Dwyer were working on the collar. rybody fears that the tube will slip into the nx. So did they. The collar was molded on r upon layer of gutta percha, to make the collar e. Again everybody who has given it thought, its the caliber must be large. So did they. to this time, no living case at the Foundling been intubated. Indeed, the word intubation not yet born. The tube had seemed to fit the yer. The first introducer I here show you, to me recently by Dr. Chadbourne of Pasadena, made it and has treasured it ever since. He s: "I made it of a metal spiral catheter, the handle of a sink cock and the handle of a walk-tick. The extractor was a long silver uterine ointed probe bent so the ball would catch in ngle of the bivalve."

e next step was to try the instrument on a child. Would the larynx tolerate a tube? yer did not, for years later, know of Bouchut's in Paris. Bouchut had demonstrated this fact—that the larynx would tolerate a tube. old hirsute and rheumatic Bridget, in charge marasmus room, occasionally wondered why of her "little dairlins" on arrival in the ward o voice. Sometimes they lost their voices in ight. On inquiring, she detected a smile on upernaturally sober countenance of her adored O'Dwyer, and the lurking smile of the house ician. Not even when she occasionally found e bed this queer collar-button-looking object he know much more of it. The tube tried on arantic babies proved the fact that the tube d be tolerated, and when autopsy was made days later it was found that the tubes had no harm to the tissues. These questions were important. The tube did not injure normal ues when worn five to fourteen days. This pattern of bivalve speculum was used a little in a child with croup and relieved the dyspnœa. d a great moment! A bivalve had been ed successfully in a child with croup and œa and had brought instant and continued This seems very tame reading in these e days. Place yourself where O'Dwyer was. vere cases of croup, which meant diphtheria larynx, had died. Every case tracheotomized ied. To the sisters of charity, well-marked meant death, and if no doctor had opportunity ddle with it death came a little earlier, but no rely, and the operation seemed cruel meddle-ess. Fancy, O'Dwyer, then, seated before an croup patient, endeavoring to insert a tube. effort choked it and made it appear about to ate. After a time his courage was strong h and his confidence great enough to make a ful introduction. The bivalve was inserted, ed dyspnœa, remained in place. Alas, the ous membrane swelling, pressed in at the sides e the blades were apart and dyspnœa again ed. One case lived many days even then, nally recovered.

gradually became evident that a solid tube replace the bivalve. Then began the various urements, changes of contour, fitting to the omy—a long study and a long stretch of time tirement. A head there must be, large enough to keep it from slipping down, not so large that the epiglottis could not close over it. The tube must be long enough to reach as near the bifurcation of the trachea as possible and avoid obstruction from flaps of loosening false membrane, short enough to sweep downward between the arch of the palate and the base of the tongue, small enough not to cause undue pressure and ulceration of the vocal cords, large enough to fit tight and not to be coughed out. Its caliber must be great enough to admit sufficient air, small enough to leave the tube structurally strong. After all this was done the epiglottis must fit the head well enough to prevent fluid from entering the tube and trachea, yet there must be no great pressure on any one spot or surface. Diphtheritic mucous membranes ulcerate easily under pressure. Problems grew as the tube approached the practicable.

If you hold a modern, perfect tube in hand, you will note that the head is triangular, beveled on one side and tilted back to fit the epiglottis. In other words, the tube head is made in the most inconvenient way. Every instrument-maker has said: "Oh, yes, I can make one just like it, I'll have it for you to-morrow afternoon." The man has not yet lived to fulfil that promise. He will tell you the tube is the same. If you ask him about the tilting back. Oh, he did not notice that, but that is of no importance. How about the smoothed-off epiglottic side or the convex up-surface or the rounded angles to fit between the arytenoid cartilages, etc.? He simply rubs his eyebrows and says that is fussiness or uselessness. Imagine the difficulties O'Dwyer had with mechanics. Finally, he found a little German who was willing to do as he was told. Alas, he was unreliable. His shop was too near a beer saloon, and his promises—well, they were too. He did much good service for the development of intubation, but became impossible to manage. We were always afraid this man would get out a patent on intubation. I have often thought I would like to hunt up this beery friend of early economic intubation days, and see if he is hungry and cold. Alas, cirrhosis probably has him by now. I'd like to soak with a long drink his poor old sodden trunk, for he did his little to help. I'd like to do him a good turn to-day for the anxieties and fears he did not then fulfil.

For five full years O'Dwyer worked on the development of the intubation tubes. The last great point was in flattening the tubes laterally, to avoid pressure on the cords, and the final triumph of all, the retaining swell. Well can I remember when the idea of the retaining swell first came to him. Then, for the first time, O'Dwyer began to feel that he would succeed fully. The tubes were loaded with plastic material and copied in metal. The successful molding of the head to fit the anatomy and the final retaining swell, brought confidence to the heart of the inventor. Five years of time, work and study, lying awake and thinking, trying on the cadaver, testing on marasmic babies, in a few cases of croup, and now, what remained? Why should he not operate on private cases in answer to repeated solicitations from those who knew of the work? The man who patiently toiled on for five years while everybody said it could not be done, even yet hesitated when all his friends had rushed to the other extreme. He would operate on a private case when he should have had one successful case in hospital—one complete recovery, and not before. Such at last came.

Then he operated outside the hospital. This case also recovered. On removing the tube the voice did not return. One week passed and no voice, two

weeks, then three weeks and the voice returned and the patient was quite well—as though its larynx had never suffered this new-fangled intrusion. At this stage one would think the happiness of the inventor would be complete. See how incomplete it was. Others began to intubate. They had all manner of accidents. Patients died in the act of intubation. Some reported membrane pushed down before the end of the entering tube, some died in convulsions. Every person having an untoward result wrote to Dr. O'Dwyer. He had letters from Naples, Munich, Budapest, from St. Petersburg and from all points to California. All the unhappy results, all tales of misadventure, and all the unfavorable criticisms came directly to him. His life was one worry. He was a poor sleeper and soon he scarcely slept at all. Modest in success, timid in venture, distressed by unfavorable criticism, worried by accidents of others—he simply died under it. He subsequently gave it as his opinion that there were no accidents of operation, except in the hands of the unskilled. See, then, what worried him. The unskilled were having patients die in convulsions from prolonged intubation—so-called pushing down of false membrane. False passages and even broken instruments were gravely reported as reflections on the operation. Some results were sheer brutality of procedure, many grotesque and inconceivable. Those who know that intubation in this country has displaced tracheotomy almost entirely from the list of operations among pediatric men, would scarcely follow me were I to tell of the bitter fights put up by tracheotomists. There were serious discussions whether the patients dying succumbed from collapse of lung or pneumonia. Any way, if intubation did not promptly do all that was ideally expected, *then*, tracheotomy was to lend its beneficial results to aid in human deliverance. All this reads like fanciful description, but I lived in the midst of it and knew it all. My poor friend O'Dwyer! His triumphs brought some satisfaction, but not unmixed joy. Often as I ran in to see him, he would shove across the table a letter, he saying not a word. Some man had bought a set of his instruments, rushed to a case, inserted the tube, and the patient had died at once. Presumption was the tubes were not only useless, but had killed the patient. Mind you. practice on the cadaver the operator had not had. The insertion of the tube may have been anywhere from the œsophagus to the ventricle of the larynx and soft tissues of the neck, with consequent obstruction. Intubation had its martyrs.

I have spoken of O'Dwyer as immortalized by intubation. I have given a rather quiet picture of his further success. Would it satisfy the young men of the J. C. Wilson Society? O'Dwyer was poor in personal and real property. He left four boys, none of whom had finished any course of education. What, then, is the use in modern days of coming to Philadelphia to talk of an immortalized inventor who died a poor man? If the question is put in that form, I retire and have no heart to answer. Let me speak my recessional:

Whatever forces wrought it, perhaps a combination of physical weakness, the mellowing influences of religion, the chastening of affliction, and the constant devotion to his motherless boys, Dr. O'Dwyer's was the most god-like character I have ever seen in man. What the world knows of this man are his genius as an inventor, his achievement in adding to the equipment of the profession a great operation. To us there is another and a pleasant duty—to testify that, with this genius, there was all that goes to make a man. His home life, his religious life, his civic life, his professional relations to colleague and patient, his hospital relations such as befit a high principled man. Wherever moved in the daily routine of life, he left little gr who delight to tell of O'Dwyer, their friend. T of us who were accustomed to go to him for ad or those who wished simply to be in his presenc the nameless pleasant influence of his person have lost a part of our lives; there is left to daily-recurring impulse, as to one in a light sle rise up and seek him out.

Highly as we esteem him as an inventor genius, highly as we rate him as a practition wide knowledge, much as we valued his su medical judgment, there is one feature we w place high above this all. We would trace upo tablet his achievements, his general knowledg medical judgment, but above them all, we w write: "*O'Dwyer the Man.*"

You were not at O'Dwyer's funeral? Then did not see the throng of physicians. You di see in the obscure light of the side aisles and seats, those uninteresting, poorly-clad women small children. To that class O'Dwyer was ticularly kind. The poor of his parish c were all his friends. They wept quietly, old w and children, head to head. As the cortege p to hearse and carriage, the street was packed b same quiet, sobbing multitude.

Why has Dr. Wilson asked to have this s story of a man's character and work set befo to-night? Why has it been considered by all an evening's contemplation?

Is it because he, because the general medic fession think in harmony, that O'Dwyer's char his methods of work and his real moral succes worth emulating?

WHAT SHALL WE DO WITH THE NER WOMAN?*

BY WILLIAM C. SEBRING, M.D.,
KINGSTON, N. Y.
ATTENDING NEUROLOGIST TO THE BENEDICTINE HOSPITA

AN eminently skilled, learned, and successful cian remarked to me once: "I feel capable of a fair amount of justice to anything from ca to corns, but may the Lord deliver me from a ous woman."

The writer believes that there is not a phy living who does not echo that man's sentimen can truthfully be said that there are no case so worry and weary, so irritate and generally f doctor's cup of woe full as does the nervous w For her there is never any twilight, the sun is blazing or else there is a gloom that is unbrok even the shadow of a light. She either walks mountain tops of exaltation or, unbefriende mankind, she weeps solitary in the valley of ness. The physician that is attending her is an absolute disgrace to his profession or else the miraculous of his kind. Most happily the la oftener the case than the former, for as a dro man will grasp at a straw if it is the only object in his reach, so will the nervous woman cling physician, if perchance, for any reason he is th physician at hand, or if there is some subtle about him that may induce her to think that his especial patient, or that he is doing more f

*Read before the Ulster County Medical Societ tember, 1903. Re-read by request, December 29, 1

has ever been attempted before in the history of cine. Make the nervous woman think that your tion is solely centered on her and she will never nother physician. But how many times have of us wished that we had chosen any other pro- n simply because "the nervous woman" had to our lot.

about a quarter of a century the practice of ry has been revolutionized: zymotic diseases, degree, have lost their terrors, and gynecology ast if we take the say so of the specialist) can t make your grandmother a maiden. A tuber- peritonitis can be cured by cutting into it, he tuberculous joint can mostly be cured by it a vacation. In orthopedics the poet's day breaking when there will be "no more halt, me, or blind." Through many generations of sive use the human eye degenerates; what mat- t, for two little pieces of glass, bound together a golden frame that is more of an ornament a detriment, will make as clear the vision as it the springtime of the race.

k to what department of medicine that you d you shall find that an art is giving place to a e, except in one. Far be it from me to say here is no balm in Gilead yet found for the us woman, but *certes* there has been infinitely me given to her by the leaders of medicine than other subject that is so important and pertin- both the patient and the physician. Perhaps e there has been so little time devoted to her e leaders, that so much time has had to be ed to her by us little followers on. Look gh the files of our most scientific medical jour- nd how much information will you be able an about her? Try it the first time you have e that you are at your wits' ends about, and cy that you will go back and see that patient very few new ideas of what to do next.

is for this reason that the writer has prepared aper, non-scientific in a sense as it is, and dis- ive, perhaps, to a tedious degree, yet he hopes if this paper presents nothing absolutely new, y refresh your attention to this subject, and if y of you it should give any hints that will make less nervous, because you have made the nerv- oman less so, neither my time nor yours will isspent.

this paper are described five cases, all taken actual practice, and they embrace the five ent classes of nervous cases that are seen often by the physician, and most often give reatest amount of trouble. They are described tually as they may be, and they will be used text for remarks on the treatment of similar

SE I.—Well does the writer recall a winter a months after he had rather shamefacedly begun practice of medicine. Over the hill he could a wagon rattling along the frozen road. As the e strikes the bridge he knows by the regular of the horse's feet that the driver is urging him ough Death had entered the race. But a short ent and the driver is scrambling up the walk e office, and without a knock almost tumbles the door, on his face was a mingled look of grief, , and anxiety, that the physician knows so well has often marked—a look that you will find on faces of bystanders while the doctor is working a person that has been severely injured during ccident; it was the same look that you will see e a household is awaiting the critical period of a erate illness.

he man was an intelligent farmer and a call been made at his home early in the day to see his aged father, who had suffered a stroke of paralysis, and I supposed that the old man had become worse. "Doctor, doctor," the man exclaimed, "something terrible is the matter with my sister, and I want you to come right along." Without questioning him I took my case and climbed into the wagon. As well as he could, between the earnest protestations to his horse to go faster, he told me that his sister had seemed very nervous through the day, and while the family were talking about the condition of their father, she had, without warning, given utterance to a sound that was half-moan and half-shriek and dropped unconscious from her chair, though as far as the man could tell she had sunk to the floor rather than fallen. After she seemed unconscious for a few moments, she passed into a convulsive condition, not apparently recognizing the family, but was constantly in motion with arms and legs, and if not restrained would roll about the floor "writhin' in mortal agony," as the farmer expressed it.

By this time we had arrived at his home and I hastily entered the house. There was found a rather plump, blonde lady, perhaps thirty years of age, lying with her head and trunk on the sofa and her legs on the floor. A stout farmer neighbor held both of her hands in his, and was vainly trying to hold them still, but he was a complete failure at the operation, as in spite of his best endeavors they were see-sawing back and forth across the woman's chest with a motion almost as rhythmical as a pendulum. Another person at the head of the lounge was holding her head clasped in both hands in the attempt to restrain the side-to-side motion of the patient's head. Squatting on the floor was an elder sister of the girl and encircled with her arms and closely wrapped to the sister's bosom were the patient's legs, in the likewise vain endeavor to control their spasmodic movements. The room was not warm, but the faces of those there were bathed in perspiration, though there was none on the face of patient herself; but rather on her face was the look and light of one "that doth see visions and prophesy," or, as Joseph Cook used to say, "illumination and levitation," a gleam that was not "of the earth, earthly." With a voice that was strident and strained she was soliloquizing after this fashion:

"O, my father, my poor father will die; what shall I do when my poor father is dead, my poor father is dead; what shall I do when my poor father is dead; and gone to my mother. My mother is dead, my mother is dead; what shall I do when my father is dead and gone to mother. I can see my poor mother in heaven. I see her face and the angels, the beautiful angels about her, I want to die and go to mother that is with the white angels." In this sort of strain she was "going on," and every muscle of her body was in motion except those of facial expression. Her sister looked up and with a piteous voice exclaimed, "Oh, doctor, Annie is going to die; she must be dying now, for she can see her dear mother in heaven." This all sounds flat enough to hear or to read, but let me tell you that to a young and new physician, with a reputation in and respect of a family with a large connection to gain, that scene was not at all insipid.

Putting a bold face on the matter, though with by no means the mental assurance with which these cases are met now, I told the sister that the patient was nowhere near translation, but that she was "suffering from a severe shock to her nervous system," and that she would be better presently. (A pretty inconsequential amount of

information to convey to the anxious friend, you may say; could you have said anything better if you had been there?)

Then began a canvas of the situation. I recall having in my notes that the proper thing to try in an acute hysterical attack was pressure on the supraorbital nerve. All right, try it then, so without opening the drug case I began an operation that must have looked very much to the family like an attempt to gouge out the patient's eyes. There was no result for a time except to produce a stare of amazement from the bystanders. Of course I had been told by a very learned professor of nervous diseases that the pain from supraorbital pressure would grow so great in a few minutes that no hysterical person could bear it. So the pressure was continued and it was not very long before,sure enough, results did begin to manifest themselves. One of them was that the patient tore her hands loose from the man that was holding them and delivered a sounding smack on the face of the medical attendant, and let me assure you there was energy in plenty in the gesture. After the assistant had secured the rebellious members, rather against the protest of the family, the attack on the supraorbital was resumed. During all this time the inhabitants of the beatific vision had been rapidly increasing and threatened to develop into a regular apocalypse in full activity. The writer had to confess to himself that pressure on the supraorbital nerve was in this case a lamentable failure.

Some other procedure must evidently be inaugurated. Drugs, some tell us, are but of little actual service to restore a hysterical subject to her senses—mechanical means are to be much preferred —so then I will try ovarian pressure. I was going to treat this case "secundum artem," though by the looks of the family a blind man could have felt that I was getting to be to them anything but the "beloved physician." So without any very lucid explanation to the family the "ovarian pressure" was begun; after a little, in spite of the best endeavors of the three attendants, the patient wriggled herself to the floor; and then the physician attempted the double work of following the serpentine gyrations of an ecstatic female about the room, and at the same time the employment of "ovarian pressure." This treatment did not last long—it just simply couldn't.

From that time my faith in the restoration to reason of the acutely hysterical, "by mechanical methods" suffered a complete solution of continuity and has never been restored. A wild idea did occur to dash a pail of ice water over the recalcitrant sufferer, but this would have been a little too dramatic even for the occasion. All this time the celestial beings were drawing nearer and nearer to the patient, and she asseverated most earnestly that she could hear them singing their celestial harmonies.

At length opening my grip I found in it fluid extract of valerian, croton chloral, bromide of sodium, and morphine. About this time the elder sister began to show marked symptoms of rebellion and inquired if "I thought I had had experience enough to deal with such a case." To be frank, I had begun to doubt it myself. The drugs given above were each tried in good doses and at last a hypodermic of three-eighths grain of morphine was given. A half hour was then allowed to elapse, but the condition of the patient was as good or rather as bad as ever. Hopelessly looking through the medicine grip for some other possible remedy to "try," there was brought to view a small bottle of terpeth mineral tablets. The writer does not know, but he has at times thought that it must have been an angel right out of that poor girl's visions that prompted t administration of two or three of the tablets.

It was but a few moments before the muscu movement began to subside, the ecstatic look fa from the face, the heavenly hosts grew fainter fainter, and wails for a dying father gave plac weak-voiced utterances that referred to a qual stomach, and—gentlemen, "If my mortal sum to such length of years should come as the m wintered crow that leads the clanging rookery hom I'll never do a smarter thing than when I got t apocalyptic creature puking. And if this paper no other use than to bring to your attention t there is an irresistible conflict between a sick st ach and an acute hysterical attack, it will not h been written in vain; for you may search fr where the Himalaya's summits are freezing un a tropic sun, to where the Orkney Isles are snuggl warm in the Gulf Stream's arms, and you will find a woman, with perverted resolutions str enough to maintain long all the *diablerie* of "h terics" if her abdominal regions are the camp ground of Gen. Nausea.

This was a stubborn case and one that might w I fancy, have given trouble to any physician. C trary to the usual teaching, the writer believes t the very best thing to do with these cases, when outbreak is of a decided mental character, that when the most prominent symptoms are displa by the mind, in the way of emotion, or even t porary delirium, is to give a hypodermic of morph It will act better and quicker than anything else large proportion of cases, but you will now and find a patient that the drug will render worse, in t case use an emetic. Frequently if the attack mild one and if you are acquainted with the pati and have some control over her, if you can find what the patient was doing just previous to the att and then in a sharp imperative tone direct her to fi the work, and this command is repeated a few tim the patient will often obey, and when her attent has been turned to the work, the attack will h ceased of itself.

I do not believe that it is worth either yours the patient's time to bother with supraorbital ovarian pressure, as it will fail far oftener than it succeed. In two or three stubborn cases more an experiment than anything else, dilatation of sphincter has been tried and it stopped the att on both occasions, but it is a procedure that is recommended, nor in a large proportion of cases it be at all feasible. First, last, and all the t remember that in 95 per cent. of the cases a hy dermic of morphine will be successful, and in the ot 5 per cent. you will never have a failure from an eme it does not matter what it is as long as it produc rather protracted period of nausea.

Case II.—A Miss R., aged about thirty-t years, but looking much younger, a blonde, rather inclined to embonpoint, was very anaem indeed to such a degree had the trouble gone th her face was entirely blanched, and when not a mated there was the dead whiteness about it th is seen on the cadaver. She had been treated b the local physicians, and at sundry times had be incarcerated in different metropolitan hospitals.

Her trouble began in young womanhood. A the time of puberty she developed attacks o severe cephalalgia. She said they had been s severe that her sight had been affected for day after an attack. Most of the time she menstruate regularly but very scantily. This condition laste from three to four years, and then she began to hav excruciating pain from the occiput down to th dorsal vertebræ. As these attacks become mor

ere and frequent, there developed a mild paresis the lower extremities. The girl at length became bridden or nearly so, and was taken to one of the w York hospitals. The writer could not elicit n her just what line of treatment was there pted, except that on the bed card was written inal irritation," and so far as she knows the tment consisted in absolute rest in bed with pplication of electricity and the ice-bag to the e. She derived but little benefit from this, at the end of three months was taken to another pital and then to another and another, and finally brought home as incurable. When first she had improved so that she was about the e a part of the time, but she did not take active part in the affairs of the household. w local physician was called in, simply because as a new man. He remembered having read where that neuralgia was a nerve crying for —which it is not always, by any means. How it that the nerves were starving?—because the d was starving, and starving blood is simply d that has not the power to absorb a normal nt of iron. This may be very shaky physi-, but it was good enough physiology for this anyway. It is likely that every physician consciously or unconsciously come to this con-n about a similar case, and no doubt iron me form had been given *ad libitem*, but had a total failure because the iron had not been bed. If you think of it, the medium from a membrane will absorb any drug most y is the saline solution. Then it stands to n that if iron could be jointed to a saline or a e compound made of it, it should be taken the system faster than any other form and you d have the remedy you are in need of.

s young lady was placed on Flint's tablets our or five of them were given at a dose every hours, and to alleviate the pain Brown-rd's neuralgia pills were used with moderation. d they seem to control the cephalalgia better anything that had been tried, and the writer ound them to succeed several times in cases of nate headache when nothing had been found ieve.

e result was very prompt, for it was but a eeks before the patient's lips began to lose pallor and a slight amount of color appeared e cheeks. In three months the woman was ly free from pain, and her cadaveric look had ne almost plethoric.

this time the tablets were discontinued for l months, but after a time the patient began pse back into her former condition, but was y restored by a return to this saline form chalybeate. For the last three years the woman njoyed perfect health, but steadily uses about of the tablets a day as this seems to be the nt required to maintain her position.

re was a case in which the nutrition of the m was purely at fault, and when this was cor-d the woman was well, but as yet there has found no remedy for the constitutional vice would not allow sufficient absorption of iron, the patient will have to go on indefinitely shing some extra nourishment for the blood

the treatment of classes of cases like this, of e the main attention should be given to the tion. This is very easy to say, but sometimes hardest to accomplish. The real trouble is the red disks are not much if any reduced in ber, but they are poor in hæmoglobin. One the theories to account for anæmia is that the sulphur that is taken into the stomach prevents the absorption of iron. Hence Blaud's pills, though they clinically do some good, do so in spite of the sulphur which they contain (sulphate of iron), and if tried in a given number of cases I am almost positive that they will fall below the value of simple powdered iron, but the latter must be used in larger doses than is commonly done. Ten to fifteen grains every three hours is by no means too large. The tincture of the chloride of iron is a nasty drug in every way and its internal use might as well be dropped. If there is a scrofulous taint about these patients the syrup of the iodide of iron will give better results. The thousand and one proprietary preparations that are on the market are no better than the regular ones and more expensive; they tend to reduce the physician's interest in the patient and the patient's interest in the physician and might as well be let alone. Possibly the albuminates of iron are an exception to this statement. In many of these cases there will be found a hyperacidity of the stomach and the iron will produce better results if bicarbonate of sodium is given at the same time. But still the preparation that experience will show to be the best the writer is positive is Flint's tablets.

In regard to other means of treatment, hygienic and the like, one can say that an existence spent largely in the open air is of great advantage, but use common sense—under no consideration should severe physical exercise be enjoined. It is worse than useless to attempt to have these patients "work up an appetite."

The "Weir Mitchell rest cure" is absolutely impracticable for the general practitioner, and it is doubtful if the real benefit from the treatment is not more from the mental impression than from the rest and manner of feeding; however, there is a small per cent. that can be raised to a higher average of nutrition by thoroughly resting in bed for a few days at given times. What shall be said about analgesics in these cases? It is cruelty to the patient to let them be deprived of them, and yet they lower the already depressed vitality. In a good share of cases the faradic current will give relief that is temporary. Hyoscyamin will sometimes do good, and with as little reaction as any of the alkaloids. The passion flower of the homœopathists will do well in a small number of cases, and is an excellent remedy, as the reaction, at least with the writer, has not been noticeable, but it will benefit a large number of patients whose symptoms are mental rather than physical, as insomnia and general mental disquietude. The old drug vibernum opulus may be tried, and it is better than vibernum prunifolium. You may lay this down as a rule, that in cases of a nervous trouble from anæmia and when a sedative has to be used, one should always use a vegetable rather than a mineral, as without exception every mineral sedative reduces the hæmoglobin.

In cervical pain the spinal ice-bag would be of use at times, but you need not expect too much of it. By the way, make it reach the entire length of the spine. If the pain is confined to the head nitroglycerin is almost a certain remedy, but it must be given in large enough doses to effect the cerebral circulation, and many will object to its use on this account. Massage has been highly tried, but it is more profitable to those who are confined in bed. In general practice it is a good thing to prescribe cod-liver oil with a little oil of wintergreen in it to partially do away with the nauseous odor, and tincture of capsicum enough to render it slightly rubefacient, and

direct that it shall be well "rubbed in." This serves three ends—that of nourishment from absorption of the oil, an improvement of the cutaneous circulation, and lastly the massage of the muscle which you will never get unless you use some simple stratagem like this. A word about the duration of treatment. Nothing will cure these patients quickly, or in every case permanently, to use a homely simile, their fire-box is not large enough for the fuel to heat the boiler, and you must make up the deficiency by adding, from time to time, a more concentrated fuel, and this is iron in a form that will be assimilated. This holds good for all these cases except those of the transitory chlorosis of puberty, and iron cures this permanently.

CASE III.—This lady was about forty years of age, of medium height, and figure light and spare. By occupation she was a housewife, but kept city boarders during the summer. She was mentally ambitious and to a degree pretentious—that is, pretentious in the better sense. She had ceased to menstruate at thirty-six, and was a mother of four children. She gave the history that fifteen years before she had an illness identical with the one about to be described.

When she was first seen she had developed a rather severe attack of facial erysipelas. During its course there formed a pustule in the auditory canal. She complained much of pain about that region of the head which was set down to the irritation of the pustule. After the erysipelas began to devervesce she commenced to have a great amount of neuralgia in different parts of the abdominal wall, though there was little real tenderness. More at the request of the woman than for any other reason, blisters were applied, and it is a fact, that they would not develop a bleb, just what control the nerves could have had on the vasomotor supply to the skin so that a blister would not work, I confess is too deep for me. After these migrating abdominal neuralgias had been continued for about three weeks, she began to suffer uncontrollable vomiting. There was but little nausea, but no matter what substance was taken into the stomach it would be expelled in a few minutes. In a period of ten days, the woman becoming very weak, rectal feeding was resorted to. This, the writer believes, was a mistake, as the woman certainly would not have starved to death and the nourishment taken served only as an offset to the rebellious stomach in the way of furnishing strength for the patient to manifest further neurotic symptoms. A person that is extremely weak will not vomit, for the regurgitant action of the stomach will degenerate into a sort of hiccough that will not expel food. I am certain of this as a clinical fact, for I have seen it demonstrated more than once.

It is useless to dwell on the medical treatment of this case thus far, for it was a total failure, more than to say that every drug that could by any ingenuity have been thought of any value was tried.

After a period of about three weeks of gastric trouble I was hastily called to the house and found that the patient was suffering from tonic spasm of the flexor muscles of the arm, which was drawn by the deltoid directly upward from the body. The muscles and their tendons seemed to be drawn almost to the breaking point. The usual antispasmodics were tried but without result, as the legs soon took on the same spasm as the arms and were flexed close to the body. During the progress of the case there had been intermittent hysterical aphonia. At length chloroform was used, and after the woman had been partly narcotized the spasms would relax for a time, but only to return. Of course the chloroform could not be kept up indefinitely, and in desperation one day, as the spasms were returning, two long hip splints were prepared and placed in position, and also the arms were placed in splints that went straight from the shoulder to the wrist. These did their work most admirably, for they kept the legs and arms extended, so that the flexors could not begin to contract, at least with power enough to cause any discomfort to the patient. This may seem a very rude way to treat the acutely hysterical contractions, but let me assure you that it is the most practical that I have been able to devise or have ever seen.

During all of this period the woman's mental condition, at least to my observation, was normal. There was nothing about it in any way that could be said to be tinctured with hysteria. The whole outbreak seemed to exhaust itself in manifestations of the purely functional, physical attributes of the body. The woman's symptoms gradually ameliorated until she returned to her usual condition of health, without leaving any trace of what might be called an hysterical tendency. You will always find that patients recover most fully when the hysterical outbreak is physical rather than mental.

In regard to the vomiting, if you have the confidence of the family the best treatment is the simplest. Just plain starvation for a period as long as the stomach is rebellious, and then give only as little food as possible; the kind does not matter. as of course there is no true failure of the stomach at all.

A blister applied to the epigastrium has been effective, and the application of electricity by a gulliform electrode is a valuable apparatus, but one that most of us will not have at hand. The kind and current of strength will have to be determined in each case by experiment as *a priori* no one can tell, though the interrupted is perhaps, the best one to try first. Cocainizing the stomach will stop the vomiting for a short time, but the effect on the general nervous condition is very deleterious.

In regard to the muscular spasm, you may be forced to resort to chloroform, but it savors too much of relaxing the patient with a club. One of the best and surest drugs is bromide of soda, but you must use it in magnificent doses. One to two ounces in twenty-four hours or even more—and if the stomach will not stand the treatment then give it by rectal injections in still larger doses. Use the injections as they are used in typhoid fever and if they are not retained, close the anus with a napkin for a few moments and the patient then will be able to retain them for a lengthy period. A tobacco poultice applied to the abdomen will always produce relaxation, but it is a harsh drug, and the writer has been alarmed at times by the depression. It is best to remove as soon as the patient begins to be nauseated as the effect will increase after the clyster has been removed. It is not worth the physician's while to try the weaker sedatives, as lupulin, musk, camphor, galbanum, asafœtida, and the like, as you will only disgust the patient and derange the nutrition of the patient to a still greater degree.

Amyl nitrite is an exceptionally sure relaxant and after the first trial or so the patient will not object to it, and it can be trusted to the patient or an attendant, as it is absolutely non-lethal in any dose that will be obtained. This drug deserves a far more extended use in all forms of spasm than it is receiving. Sulphate of curarina is very effective, and no deaths have been reported from its use. An injection of a seventy-fifth of a grain may be given every three hours, but you must watch it very closely, and if there is any embarrassment of the respiration di

ontinue it immediately. Do not employ curare, as ou cannot be certain of the effects of the drug. his agent is of the most service in desperate cases which the contractions are verging into hysteroileptic convulsions.

In passing, let us say that a case of this sort will ways be overrun by all the busy-bodies that are hand, and if they are allowed to see the patient, e exhibition will be closed with more difficulty n when solitude, or as near it as possible, is enced on the patient.

In recapitulation would place before you these ur remedies: (1) Bromide of sodium in very ge doses. (2) Tobacco poultice, used cautiously.) Amyl nitrite, used *ad libitum*. (4) Splints; and m personal experience I believe that they are the st effective of the list.

CASE IV.—This woman was about thirty-two rs of age, strong and robust and of excellent nily history, except that her father, though a very od and prosperous farmer, was slightly eccentric the way of magnifying trivialities and the like. ere was no true neurotic taint in the family at all. is woman had been well reared on a farm, was rried happily and was the mother of one child. ntally she was above the average and of genial position, she had left home about three years evious with her husband to engage in business in w York. She had to be at their place of work at ee o'clock in the morning, which meant she must e at two. Her hours of work were very long and did not return to her home until four in the afternn. This continued the year round, without any p for Sundays or holidays. She also said that she constantly on the "*qui vive*," as she had more n the usual reasons for wishing the business to be uccess.

The history of her present illness was that she med in her usual health until she returned to her her's house for a short vacation, when she began develop migrating neuralgias; then dyspepsia th a dark-coated tongue. She rapidly seemed to e strength, so that she did not leave her bed. Her petite was poor and capricious. Insomnia was sent, but not to a great degree. The diagnosis her attending physician was typhoid fever. (By way, the confounding of typhoid fever with rasthenic conditions has come under my notice ee times in five years. The other two cases were nged around and typhoid fever was thought to "nervous prostration.")

Here the writer will say a word about hysterical mperatures in general. It is a very ticklish subt, and but little is written about it in the textoks, and at best is a good deal of a mystery. You ve all noticed that with two children, with exactly e same form of indigestion, one may develop wellrked nervous phenomena, such as twitching of the dons, slight delirium, strabismus and the like, hile the other infant will not. And if you take te you will always find an elevation of temperature the former cases and not in the latter. It therere stands to reason that the temperature was proced directly from the nervous system and not by e indigestion itself. This is said because there e some who seem to think that the nervous system not capable of itself of producing a rise of temrature, and I argued so at one time myself. nother case in which the nervous system does proce a temperature above normal is during the coma at follows an attack of epilepsy. Many cases are n record of very high temperatures that have had a eurotic cause, and these have usually been exlained on the theory that the patient has been malingering, and by a sort of slight of hand (to use an Hybernicism) raised the temperature in the axilla and rectum. The explanation that they do it by pressure or friction (though the writer does not doubt that some have said they did it in that way) is not true; try it yourself and you may press the bulb of the thermometer between your fingers until it breaks and you will get no result, and the highest you will be able to raise the temperature by friction will be to about 104° or 105°.

You may classify hysterical temperatures under two heads:

First: Those cases in which there are sudden fluctuations in the temperature, now well up and then shortly down below normal. When they are below normal do not mistake for "nervous chill," as that is almost entirely subjective with the patient, and the thermometer will show no actual fall below normal, or but very little. This condition is one that the patient soon recovers from.

The second is a condition in which the temperature is very high and does not fluctuate. It is produced by an accident or some very severe shock, and when it does occur it will be found to continue for a long time and recovery to normal is very slow and very gradual.

The case that is being described was of the former character, and grouping all the symptoms together, it does not seem that the attending physician by any means displayed very great ignorance in his diagnosis of typhoid fever.

When first seen by the writer the patient had been out of bed for a few days. Her condition was much the same as when first ill, except that the mental symptoms were much more marked. She would alternately laugh and cry several times a day. She could or would not figure correctly. She said she did not recall how long she had been sick, but thought a very long time. She was certain at times that she never would recover, and at others would deride herself saying "she knew she was acting like a baby," and so forth. At no time did she have any real delusions. Inclined to be restless, would want to go out of doors and would then return directly into the house. Her husband and child were of secondary importance. Her whole thought was centered upon herself. One day she would make plans to go to a hospital or sanatorium, and the next day would resolve to be treated at home. Sometimes the doctor did not pay her attention enough, and at other times he saw her too often and was just running up a bill without doing her any good. A careful physical examination failed to reveal any organic trouble of any description, but there was, as there always will be, found with these cases, an obstinate constipation.

This case is used as one that is typical of neurasthenia that has been produced by long-continued strain and overwork. This case had a very tedious voyage to recovery. Citrate of iron, quinine and strychnine, with stomachics, were tried, but with little result. Physical examinations were made and always a positive prognosis of recovery given. This is a good thing to do on account of the moral effect on the patient. The physician should always be optimistic with these cases, but let him never set a definite period for restoration, for if he does and the prophesy fails, not only does the patient lose courage, but what is worse, he will lose faith in the medical attendant. All sorts of drugs were tried with the woman, and the writer was getting almost as discouraged as the patient—in fact, he had nearly completed arrangements for her removal to a sanatorium when, as a last resort, he prescribed fluid extract of avena sativa. The drug had been taken but a few days when the patient changed her mind

about the sanatorium, and I fancy that no case of neurasthenia ever made a better or quicker recovery, than did that one. This remedy has been tried in similar cases often enough to satisfy me that of all the nervine drugs, it is one of the best in elevating the depressed nervous system.

About the only hygienic measure that is practical is to give the patient a sponge bath with saline solution, and then run over the body with a sponge wet with alcohol. Have this done before she arises and keep her covered with a sheet or the bed-clothes for a time; for if these cases are depressed with anything like a chill in the morning, that day will be lost to them.

If the patient is suffering depression of spirits that borders on melancholia, anholiaum Lewinii, or mescal buttons in 7 to 15-grain doses will be of service. The nucleins will do especially well when the condition is of a chronic nature. Sumbul is rather going out than coming into use, but it is a drug that will repay a trial. It is well to have the patient of this class drink a cup of tea made from 30 grains of sterculia every three hours. This is well relished, and as a rule well borne, and will produce fairly quick results, though rather temporary in character, but the tea must not be continued too long.

Just a word in closing. You may have noticed that I have confined this paper almost entirely to the use of drugs, and that is just what the general practitioner will have to do, for however well others who devote much time to these cases may do without the aid of drugs, yet the regular practitioner, if he is a therapeutic nihilist, will be a therapeutic failure.

About the reproductive organs and their relation to the "nervous woman" there has been nothing said, because with every case the writer sees, there grows a more and more profound distrust in the dependence of these conditions upon affections of the sexual organs; and be very slow to turn these cases over to a specialist in the diseases of women.

It is as old as Virgil that "they win because they think they can," and in these cases *you* win because you think you can, and if an attempt in one way is a failure, then try another, and another and another, until somewhere or somehow you will find the potent remedy, for there is nothing that will bring the personal and general approbation to the regular physician as the restoration of peace to a household that has been plagued with a "nervous woman."

Mosquito War in Ecuador.—An active campaign against the spread of yellow fever and malaria, involving the destruction of mosquitos, has recently been started at Guayaquil, Ecuador, as the result of suggestions of Dr. Gruver, the resident officer of the United States Public-Health and Marine-Hospital Service.

THE RECTAL SEGMENT OF THE URETER

By BYRON ROBINSON, B.S., M.D.,
CHICAGO.

THE topographical relation of the ureter to the rectum is significant from the standpoint of diagnosis and surgical intervention. In order to secure some standard data of ureteral and rectal relations a number of subjects, male and female, were dissected from others the pelvic organs with ureters, blood vessels, and peritoneum were removed intact, di

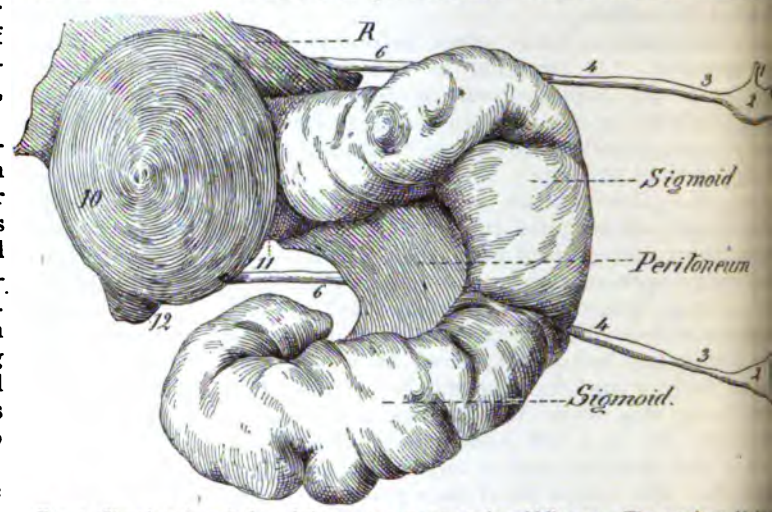

FIG. 1. Showing the relation of the ureters to rectum in middle age. The specimen, bladder, rectum, sigmoid, ureters and related peritoneum were removed from the subject and distended moderately with air and allowed to dry. Dr. Wm. E. Holland then photographed and sketched it. The parts are in the natural position. Fig. 1 is a ventral view. 1, 1, calyces. 2, ureteral pelvis. 3, proximal ureteral isthmus. 4, lumbar spindle. 5, the middle ureteral isthmus is obscured by the sigmoid flexure. 6, pelvic ureteral isthmus is obscured by the bladder. Rectovesical fold. 10, bladder. 12, prostate. The ureter courses parallel to the fossa intersigmoidea. The relation of the rectum and sigmoid to the ureters is intimate and extensive during a distending colon. While distending the specimens with air they were allowed to take their own position governed by the peritoneum.

tended by air to varying degrees, and allowed to dry—thus presenting permanent fixation relations of ureters and pelvic organs, especially the rectum

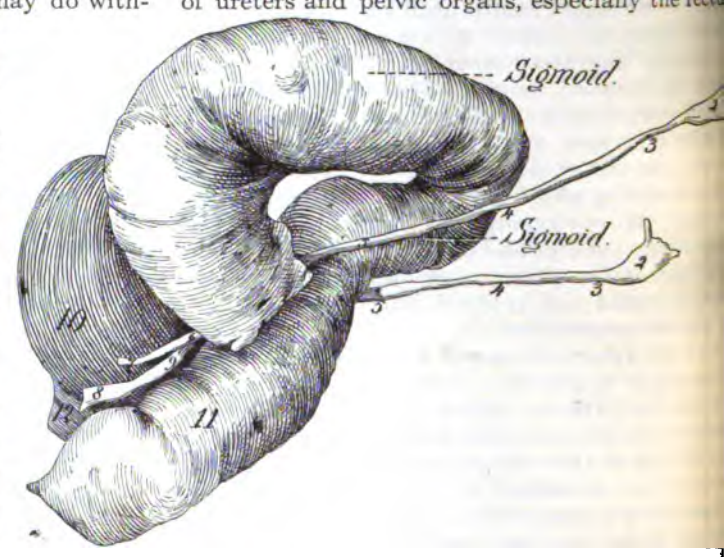

FIG. 2. Same specimen as Fig. 1, viewed from the left side. 8, vesiculus seminales. 9, vas deferens.

in varying states of distension. The results of this investigation have convinced me that the rectum is more intimately related to the ureters intraperitoneally, and especially extraperitoneally, than generally recognized.

1. The relation of the ureter to the rectum varies according to sex. The male ureter is more intimately related to the rectum than that of the female because in the female the vagina intervenes between rectum and distal ends of ureter. Besides the female pelvis is larger. The distal ends of the male ureter inbedded in cellular tissue rest in direct contact with the rectum. Hence the explanation of pa

uring defecation of large hard fecal masses when he vesiculæ seminales or distal ureters are inflamed, specially by the penetrating gonococcus.

2. Also the close proximity of rectum to the vesiculæ eminales and ureter explains the emission of semen uring defecation of large hard fecal masses and pain in he distal ureters if calculi exist.

3. The relation of the ureters to the rectum varies cording to the resting (contracted) or distended unctionating) state of rectum, vagina, and bladder. f the bladder alone be distended he ureters pass proximalward nd recede from the rectum. If he rectum alone becomes dis-nded the ureter becomes applied o the rectal wall more and nore, both extraperitoneally nd intraperitoneally, where a ouble peritoneal layer intervenes etween rectum and ureters. If he vagina becomes distended he ureteral application to the agina is increased—as much as e and one-half inches. Col-sed conditions of rectum in-ce the ureters to recede from ctum.

It is remarkable how dis-tion of the rectum increases application of the ureters to rectal wall, both at the proxi-l (sigmoid) and distal ends the lesser pelvis. Distention of rectum, vagina, d bladder forces the peritoneum of the bladder a markable distance proximalward, allowing safe dominal and bladder incisions to inspect the gone and also to manipulate the distal extra-itoneal ureteral ends. Distending the bladder one, and especially in company with rectal dis-tion, increases the length and breadth of the ctovesical fold and consequently increases the e of Douglas' cul-de-sac.

4. The ureters assume intimate and extensive dorsal vaginal walls, which practically excludes any intimate relations of ureters and rectum. The rectum makes a flexion in the cul-de-sac of Douglas, well shown in distended dried specimens with concavity directed to right which produces irregular bilateral space relations of ureters and rectum. The great rectal ampulla is located almost entirely distal to the ureters. With distended bladder and rectum (man) the ureters are over a finger's length proximal to anus. In man with distended rectum

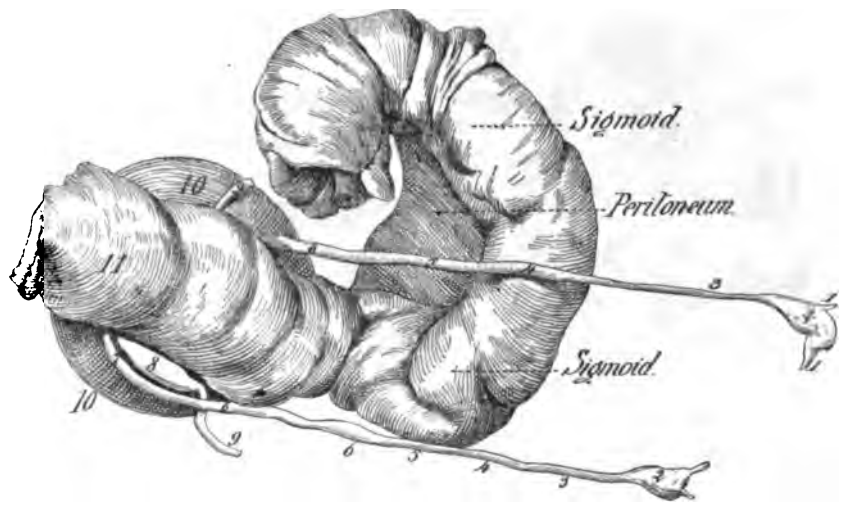

FIG. 3. Dorsal view of Fig. 1. The numbers refer to similar structures. The isthmuses and spindles show distinctly.

and bladder the pelvic ureters lie practically in contact with the rectum, and the rectovesical folds forcibly hold the ureters apart; the ureter rests against the rectovesical fold for two or more inches during distention.

In some subjects (male) with distended bladder and rectum, the ureter will lie extraperitoneally for four inches in contact with the rectum (and portions of sigmoid), after which proximalward the recto-vesical fold will receive the ureter, forcing two peritoneal layers between it and rectum. In the distal pelvis the right ureter has more intimate contact with the distended rectum because the rectal flexion located in Douglas' pouch has its convexity directed rightward. The distended rectum is frequently three inches in diameter, and hence practically fills the space intervening between the pelvic ureters. Proximalward movements of the pelvic peritoneum forces the ureters and rectum close together.

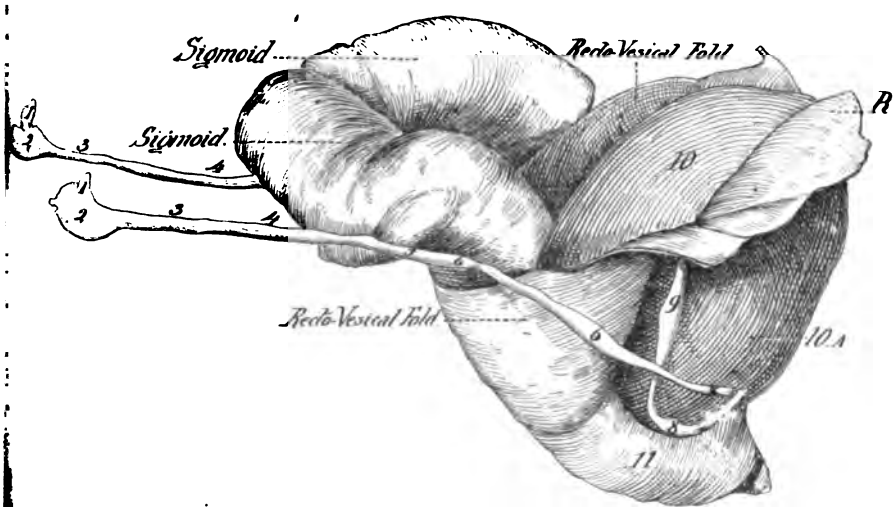

FIG. 4. Right lateral view of Fig. 1. The figures refer to similar structures. 10A is the non-peritoneal surface of the bladder. R, peritoneal folds of the bladder.
Dr. Wm. R. Holland sketched figs. 2, 3, and 4.

5. *Skeletopically* the most important bilateral relations of the ureters to the rectum is located at the level of the spina ischiadica. The level of the iliac spines correspond to the level of the ligamenta sacro-uterina. The iliac spines correspond to the ureteral elbows, the widest point of separations of the pelvic ureters, or the point where the ureters bend medianward on their journey to the bladder. These spines and ureteral elbows are on a level with the sphincter vesicæ interna. Finally the rectum and ureters approach the closest to each other bilaterally at the ischial spines or ureteral elbows. A distended

ilateral relation with the rectum (or sigmoid) im-ediately on entering the proximal part of the lesser elvis. The left ureter is separated almost an inch rom the rectum at the pelvic brim, while the right reter lies about one and one-half inches from the ectum. At the level of the distal ureteral orifices he ureter is separated from the rectum (man) right ne-quarter of an inch; left, one-half inch. In the female the distal ends of the ureters are separated from the rectum by the thickness of the ventral and

rectum gradually lies against the ureters with two peritoneal layers intervening proximally and no peritoneal layers intervening distally—where the ureters lie imbedded in connective tissue.

6. The *sagittal curves* of the rectum and ureters correspond in the proximal end of the lesser pelvis, *i.e.* the sacral rectal and sacral ureteral curves correspond and practically are bilaterally parallel.

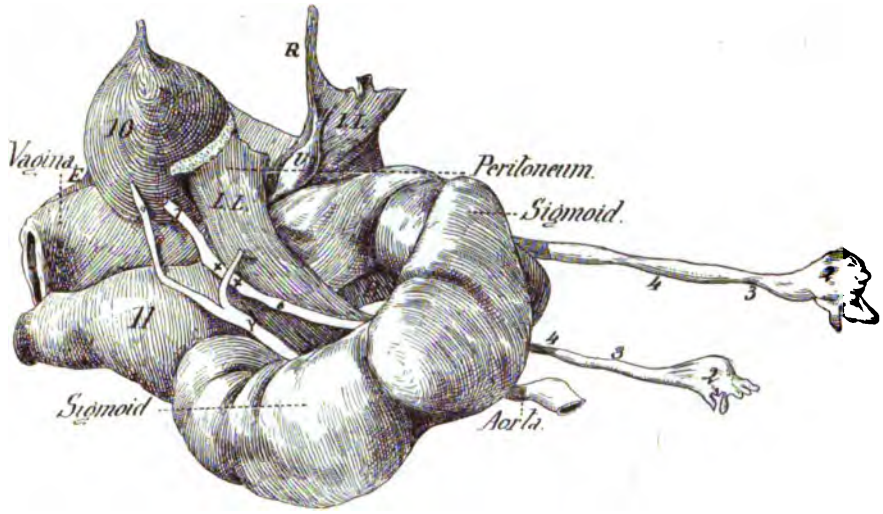

FIG. 5. Illustrates left lateral view of the bladder and ureters, the vagina, rectum and sigmoid distended with air and dried. The specimen with accompanying peritoneum and blood-vessels were removed from a subject about forty-five years of age. The hollow viscera (excepting the blood-vessels and oviducts). Moderately distended with air, being retained in normal position by the peritoneum, blood-vessels, ureters and subserosum. Subsequent to drying it was photographed and outlined by Dr. Wm. E. Holland. It presents excellently the relation of the ureter to the rectum. (6), vagina and bladder at (7). The bladder (10) is thick-walled and not widely distended. Y is the branch of the internal iliac artery which emits the uterine as it crosses ventral to the ureter at the Latin crosses (+ +), and also emits the vesical artery (O). L, L, rectovesical fold is merged into the ligamentum latum. U, uterus. R, round ligament. E, urethra. 11, rectum. B, mesosigmoid. 2, 2, ureteral pelvis. 3, 3, proximal ureteral isthmus. 4, 4, lumbar ureteral spindle. 6, pelvic ureteral spindle applied a long distance to the rectovesical fold. The left ureter is an inch shorter than the right. I am indebted to the courtesy of Dr. W. F. Duckett for the specimen.

The concavity of the proximal rectal and ureteral curves are directed ventralward. In the transverse plane the curve of the rectum located in Douglas' pouch does not correspond to the ureteral curves. This curve forces the rectum into irregular space relations with the ureter.

The distal pelvic sagittal ureteral and rectal curves do not correspond; the concavity of the distal rectal curve is directed dorsalward, while the concavity of the distal ureteral curve is directed ventralward. The distal segments of the tractus genitalis, the vagina and pudendum intervene between the angle of the dorsalward directed rectum and ventralward directed ureters. The rectum is directed dorsalward, the ureter ventralward, and the space formed by the acute diverging angle is occupied by the vagina and pudendum, important data in hysterectomy per vaginam and distal rectal operations.

7. The ureter may be palpated per rectum. The guides are: (1) the internal iliac artery and (2) the iliac spine. The ureter may course: (*a*) ventral; (*b*), dorsal; (*c*), medial to the internal iliac, the pulsation of which may be felt, after which the palpating finger feels for a projecting, resisting cord, which will be the ureter, estimated by its size, course, consistency, and mobility.

8. The ureter may lie quite close to the lateral pelvic wall or be located quite a considerable distance from it in a loose bed of cellular tissue. Hence in palpating the ureter per rectum one may need to palpate many strokes with the finger before it is certain that the ureter is felt. Per rectum one can palpate the ureter from the iliac segment where it crosses the vasa iliaca by invaginating the perineum proximalward, whence the finger is passed to the bifurcation of the common iliac to locate the ureter by arterial pulsation. In abdominal operations when the peritoneum is incised, the ureter may be recognized close to the rectum by manipulating the cellular tissue between the finger and thumb, it requires, however, time to be sure of the structure, calling to aid the sight color, direction, mobility, and consistency of the ureter.

9. The ureter in its distal three inches is accompanied by a distinct fibromuscular sheath, which makes it larger, more easily palpated, facilitating the finding of its direction or course and lessens the danger of ureteral trauma from incision, ligature, or clamp. In operations per vaginam or per abdomen the introduction of ureteral catheters facilitates the recognition of the ureter during the surgical procedure.

10. The severed ureters in surgical procedures should always be introduced into the rectum as infectious processes will in all probability, as proved by experiments, pass proximalward through the ureter to the kidney, through the cribrum Bellini into the tubuli uriniferi, creating nephritis.

11. In extensive operations on the rectum, as Kraske, operations for carcinoma on the proximal end of the rectum the ureters are in danger of trauma, incision clamp, or ligature. They should be forced by traction forceps from the operative field.

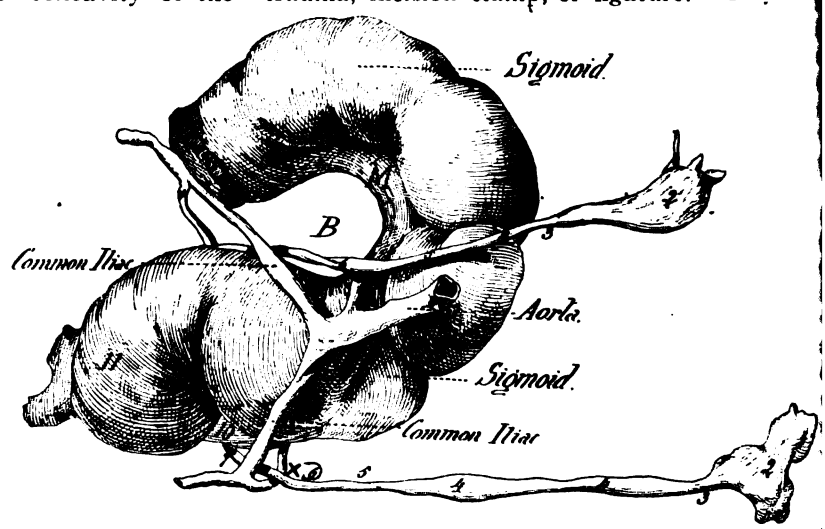

FIG. 6. Illustrates a dorsal view from the same subject as Fig. 5. Note the rectal ampulla extends chiefly distal to the point where the rectum is intimately embraced by the ureters, hence the ureters escape damage during operations on the distal rectum. The ureteral spindles (4, 6), and isthmuses (3 and 5) present distinctly. The rectal and ureteral typography are presented in natural position. Observe the flexion in the rectum at 11, which alters space relations of the ureters and rectum.

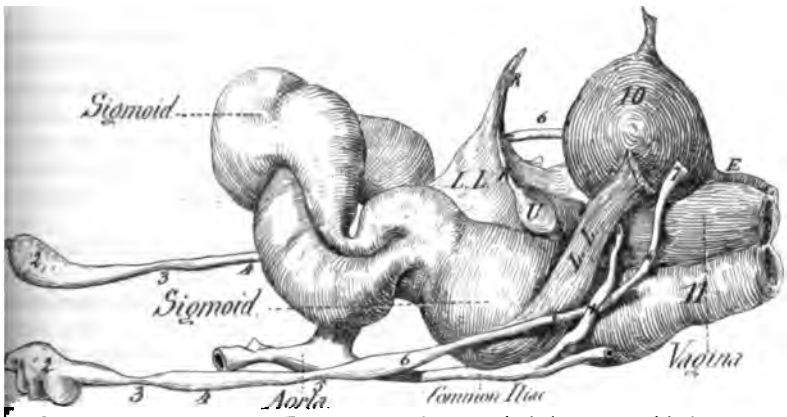
12. In general, the ureters and rectum are not parallel in the pelvis; the ureters follow the curve and lateral pelvic wall, while the proximal rectum follows the sacral curve. However, the ureters converge at the pelvic outlet. The ureters approach the lateral and ventral rectal wall similarly with

· approach to the vagina. In the relation of ureters to the rectum it is well to remember the rectum is covered ventrally with peritoneum ly more extensively than dorsally, and that the of the ureters as regards distention of pelvic ra is between the blades of the uterosacral vesical ligaments (woman) and rectosacral and al ligaments (man). This wide range of ureteral ements in the rectal and vesical peritoneal



7. Right lateral view of Fig. 5. The ureter 6, 6, lies extensively in contact with the rectum. also a long vaginal contact. The Latin + represents the distal arterioureteral crossing. Wm. E. Holland sketched figs. 6 and 7.

ents is excellently demonstrated in the dis- on of the bladder, rectum, and vagina with air. e rectal segment of the ureter possesses a ct fusiform spindle, hence if this segment es severed during an operation it has ample and lumen to perform ureteral anastomosis by the stove-pipe method adopted by the or or the Van Hook method of implanting the l end of the proximal segment into a lateral of the distal segment.

E TECHNIQUE OF THE REMOVAL OF ONE-HALF OF THE THYROID GLAND.

By JOHN G. SHELDON, M.D.,
GEON-IN-CHIEF TO THE MINERS' HOSPITAL, TELLURIDE, COLO.

T surgeons follow the same method of operative cedure in the removal of part of the thyroid gland. descriptions of the operation in textbooks and cles on the subject are worded in practically the e language. The description by Curtis[1] gives us technique of the operation as it has been described years in whatever has been written on the sub- t. His description is as follows:

"The operations were all performed in the same y. The gland was usually exposed by a trans- e incision, the superior thyroid vessels tied, the d retracted inward after ligation of superficial s, and the inferior thyroid vessels secured, the ery usually being tied near its origin, the isthmus n divided, leaving a generous layer of gland ue over the neighborhood of the recurrent yngeal nerve. The isthmus was sometimes shed and ligated *en masse* with catgut, some- es divided with a cautery."

I can find records of deviation from this method, ported by two English surgeons: Jacobson and ward[2] ligate the superior thyroid artery and then ide the isthmus before ligating the inferior thyroid. Pearce Gould[3] advises division of the isthmus as first step in dealing with the gland. The thod of Bose and Poppert—elevating the gland d constricting its base with a rubber tube—is, believe, impossible to do in the great majority of es.

The method that I have followed for some time, doing these operations, is practically the same as at advised by Gould. I have found it easier, fer, and more rapid than is the operation when done as is generally advised. For these reasons, and on account of the little attention given to Gould's procedure, I think it timely to call the attention of operators again to his method.

The operation, as I have performed it, is as follows: The gland is exposed by dividing the skin, fascia, and muscles. The next step is to pass a Kocher's director or one blade of an artery forceps between the trachea and the isthmus. Usually, I remove the isthmus, and in these cases clamp the gland with a stomach clamp between the isthmus and the lobe that is to be left. When one clamp has been applied, a second one is placed close to the first and an incision made between the two clamps. I now turn the isthmus and the lobe to be removed outward and separate the under surface of the gland from the underlying structures with the finger covered with a piece of gauze. This can be easily and quickly done without injury to the gland or to the structures on which it lies. The thyroid arteries are soon exposed as they enter the under surface of the gland. If a transverse incision has been made the inferior thyroid is first exposed and clamped; if an angular incision has been used, it is easier to expose and clamp the superior thyroid before dealing with the inferior vessel. After the arteries are clamped close to the gland and cut, the removal of the remainder of the lobe is easily accomplished by blunt dissection close to the gland. The veins of the thyroid do not bleed after the arteries have been clamped; and the internal jugular vein, in the great majority of cases, gives no trouble.

The advantages of this method of procedure are best seen when the difficulties of the operation are considered. The main difficulties in operations on the thyroid are: (1) hemorrhage; (2) injury to the recurrent laryngeal nerve, and (3) expression of the contents of the gland by manipulation of the organ during the operation.

Hemorrhage.—The superficial veins near the median line of the neck usually give little trouble. They are easily clamped. The veins on the outer surface of the lateral lobe are troublesome if injured; but they are not disturbed, when the gland is removed from within outward, until the arteries are clamped. Then they cease to be a source of annoyance. If the internal jugular vein is in an abnormal position and is found anterior to the lateral lobe of the gland, as was the case in a patient operated on by Jessop and Berry,[4] it can be quite easily observed and avoided by the method herewith advised. It will be the only vein on the outer surface of the gland that does not collapse after the arteries have been clamped.

The arteries are more easily and quickly exposed and clamped when the dissection is done from within outward. If the thyroid ima is present, as it is in 10 per cent. of all cases, according to Treves, it is easily observed and gives no trouble. The superior thyroid artery is always superficial to the common carotid and is easily found at the upper part of the lobe. The inferior thyroid artery passes behind the common carotid and becomes superficial to the inner side of that vessel. It enters the gland close to the trachea and only a short distance from the median line. In most cases its branching is distinctly seen before it enters the

gland. If the lobe to be removed is large, the enlargement is always external to the part where the artery enters the gland. I have found that the inferior thyroid artery is as easily exposed from within outward in cases of excessive enlargement of the lobe as it is in cases in which the gland is nearly of normal size. When the artery is exposed from the outer side of the neck, an enlarged gland makes the procedure difficult and frequently bloody. When the operation is done from within outward, the arteries are exposed and clamped without disturbing any veins.

Injury to the Recurrent Laryngeal Nerve.—The recurrent laryngeal nerve lies close to the inferior thyroid artery and may be either internal or external to it. I have experienced no difficulty in avoiding the nerve when I have done the operation as herewith described. If the nerve passes between two of the terminal branches of the artery—as was observed by MacCormac—I think it can be dealt with more easily, quickly, and safely by the method I have described than it can by approaching the arteries from the outer side.

Expression of the Contents of the Gland by Severe Manipulation of the Organ During the Operation.—My experience has been that the thyroid can be removed with much less injury to the gland, by the method herewith described than by performing the operation as it is ordinarily described. This is obvious from what has been said in the foregoing concerning hemorrhage and the position of the arteries.

There may be some disadvantages in the method that I have advised, but so far I have not experienced them. If the isthmus should be bound so firmly to the trachea as to render its separation almost impossible, as was observed in one case by Spencer, it is possible that the gland might be attacked more advantageously from the outer side. I am of the opinion that conditions such as are described by Spencer are very rare in non-malignant cases.

I have purposely said nothing about anæsthesia, incision, or drainage. I use chloroform in most cases; local anæsthesia was used in three cases in which there was pronounced dyspnœa. The patients did not complain as much as I anticipated. I have used the transverse incision of Kocher in all but two cases. In these the gland was very large and Kocher's angular incision was made.

I believe that tubular drainage, for ten or twelve hours, is advisable in all operations on the thyroid for two reasons: (1) A considerable amount of primary wound secretion is exuded; and (2) the contents of the gland may have been expressed into the wound during the operation.

The Dependence of Aural Affections upon the Nose and Throat.—The views of H. E. Smyth are expressed in the statements: (1) That while nasal diseases predispose to aural affections, there is less direct danger than is generally supposed. (2) That excepting specific infections, the greatest danger is from diseases of the nasopharynx. (3) That many of the ear affections accompanying nose and throat disease may be due to a general tendency, rather than a direct extension. (4) That to treat aural affections successfully, it is a wise precaution to examine carefully the nose and throat, and correct as far as possible all pathological conditions.—*The Laryngoscope.*

TWO CASES OF SPLENOMEDULLARY LEUKÆMIA, TREATMENT, AND RECOVERY.

By BERTRAM L. BRYANT, M.A., M.D.,
BANGOR ME.
VISITING PHYSICIAN TO THE EASTERN MAINE GENERAL HOSPITAL;
AND
HAROLD H. CRANE, M.D.,
BANGOR, ME.
INTERNE IN THE EASTERN MAINE GENERAL HOSPITAL.

In the MEDICAL RECORD of August 22, 1903, we read with great interest an article by Dr. Nicholas Senn entitled "Case of Splenomedullary Leukæmia Successfully Treated by the Use of the Röntgen Ray." This case he had treated unsuccessfully for three weeks, using Fowler's solution and iron, and attributes the recovery of the patient entirely to the use of the Röntgen ray. The author also makes the statement that this is the only case in which he has seen recovery.

We wish to report two cases that have come under our observation during the past year.

CASE I.—The patient, a married woman, thirty-three years of age, was admitted to my service September 29, 1903. Family history negative, both parents alive and well. Patient never has been strong or well. She had stomach trouble when a young girl and frequent bilious attacks. Had diphtheria, measles twice, and frequent attacks of acute tonsillitis. About eight years ago she had catarrhal enteritis, and was very ill for several weeks and never fully recovered. Has had one child in good health and no miscarriages. Temperature on admission 99.6°, pulse 88, respiration 35.

About one year ago she began to have pains in the left side of the abdomen over the spleen. The pains were lance-like in character, and patient would suffer great agony while they lasted. She began to feel weak and lost about twenty pounds in weight. The attacks of pain became more frequent, but not so severe as at first. Some time after the first attack she began to have pain at the ends of the long bones, more especially in those of the arms. At this time she noticed an enlargement in the left hypochondrium and experienced dragging sensations in that region. Menstruation became irregular and the flow very scanty, until now it has entirely ceased. Her bowels are very loose, moving from two to four times daily. Her appetite is voracious. She has frequent severe headaches, is very nervous and cannot sleep at night, and is unable to attend to her household duties. She is emaciated and extremely anæmic. The spleen is greatly enlarged and extends two inches to the right of the umbilicus and three inches below, practically filling two-thirds of the abdominal cavity. Its free borders can be easily palpated. Vaginal examination negative. Urine is cloudy, acid, sp. gr. 1.033; album in a trace, sugar none. Urates, phosphates, and epithelium from bladder.

Blood examination: Hæmoglobin, 50 per cent.; reds, 3,500,000; whites, 176,000. Stained specimen myelocytes predominating, eosinophiles greatly increased; poikilocytosis, few nucleated reds.

Treatment: Fowler's solution gtt. v, t. i. d. increasing one drop daily. Blaud pills gr. v, t. i. d. Exposure to Röntgen ray of area over spleen and ends of the long bones for ten minutes every other day.

October 12. Blood examination: Hæmoglobin 60 per cent.; reds, 4,000,000; whites, 55,700. Stained specimen, myelocytes greatly diminished, eosinophiles scattering, polynuclears predominating.

October 25. Röntgen ray suspended since October 12, as it made the patient very weak. She

nausea, headache, and extreme nervousness palpitation of the heart.

ctober 26. Röntgen ray resumed. Sodium nide gr. xx t. i. d. was ordered.

ovember 1. Blood examination, hæmoglobin, er cent.; reds, 5,000,000; whites, 4,500. Stained imen; white cells in normal proportion, red eated cells absent. Spleen has contracted to ly normal size. Patient is still nervous and less and easily excited. All pain in the long s has disappeared.

ovember 10. Bromide omitted, Fowler's solu- cut down from gtt. xxx to x.

ovember 16. Blood examination shows the d normal. The spleen extends a little below twelfth rib.

ovember 21. Patient discharged practically re- red. She became an out-patient and received tgen-ray treatment twice weekly. Fowler's tion continued in ten-drop doses, not increased.

ovember 27. Patient looking well; has con- rable color in her cheeks and is gaining flesh. eeping out of doors on pleasant days. Appetite cellent, and she says she feels better than she for years.

ASE II.—This patient was admitted to the hos- l February 16, 1903, during the service of Dr. H. Simmons, through whose courtesy I had y opportunity to examine him at that time since his discharge. Man, age thirty-one, un- ied. Family history negative.

r the past three or four years he had been g in health. In 1898 both arms suddenly be- e covered with an eruption of blisters which e and discharged large quantities of serum. t that time he began to cough and raise a t deal. He began to notice an enlargement e abdomen the latter part of 1899. In Febru- 1900, the tumor in the left side began to grow . His legs were œdematous and then his e body. He was always troubled with con- tion. He was admitted to the hospital suffer- rom a hæmatoma of the right ankle, the result n injury a few months before. The ankle much swollen, the œdema extending to toes. The patient was very anæmic, weak, short of breath. Abdomen greatly enlarged. splenic tumor extended into the pelvis and to right two or three inches beyond the umbilicus. d examination showed: Reds, 3,300,000; whites, ,000; chiefly large myelocytes; eosinophiles, and w nucleated reds. Urine: light yellow, sp. 1.017; albumin a trace, no sugar. Sediment, es, few uric acid crystals, no casts. The matoma was incised. Fowler's solution in in- ing doses was given, together with bone- row and iron. He was discharged March 6, roving rapidly in strength, although his blood nt remained practically the same. He re- ed ten days later, when the hæmatoma was n incised. Remained in the hospital four days, roving steadily. He thought the iron did not e with him, so left it off after taking a few doses, t continued with the arsenic until the following y. Gained in health and strength rapidly. e 1st of August he noticed that the splenic mor began to soften and rapidly disappear. On tober 12 he came to my office. His cheeks were l and he had every appearance of health. Said could not remember when he had been so well. s blood on examination showed hæmoglobin, per cent.; reds, 5,300,000; whites, 6,400. Dif- ential count showed normal proportions; myelo- tes and nucleated reds had disappeared. On mination of the abdomen the tumor was found to have entirely disappeared, and the spleen was of normal size. The man had entirely recovered.

It is unfortunate that in both Dr. Senn's and in our own cases arsenic was given as well as the Röntgen ray. In Dr. Senn's case Fowler's solution was given for three weeks before the other treatment was begun. In our first case it was continued throughout the treatment. In the second case it was all the treatment the man had. It is a question as to how much good the ray did in these cases. It seemed to us that it hastened matters in the first case. The woman had been under treatment but a very few days before there was a very noticeable diminution in the size of the spleen, followed by a severe constitutional reaction; while the second patient improved slowly with no marked disturbance, but the tumor did not begin to disappear until three or four months after the beginning of treatment.

The "Long" Lactic Acid Bacilli Found in the Urine in a Case of Gastric Carcinoma.—Rudinger describes a case of colloid carcinoma of the stomach with metastases in the liver, the omentum, the retroperitoneal glands, and the renal pelvis. It was possible to obtain pure cultures of the "long" bacilli of Boas from the gastric and intestinal contents post mortem and from the urine during life. The author explains the occurrence of the bacteria in the urine as probably being due to the fact that owing to the renal metastasis there was a considerable admixture of blood to the urine which made it a good culture medium for the organisms, which presumably gained access to the bladder from the perineum as the patient was a woman and had incontinence of fæces for a week before death.—*Zentralblatt für innere Medizin*, 1904. No. 5.

Registration of Nurses and Nursing Homes in Great Britain.—A bill to this effect is being promoted in Great Britain. The bill is to provide for the registration of nurses and to prevent anyone practising as a registered nurse unless registered under a penalty of £10 ($50). Existing nurses are to be registered on production of evidence of training, and so are colonial nurses under certain conditions. It is proposed to constitute a central board consisting of medical practitioners and nurses, to control and regulate the nursing profession and publish the Register. The board will also have power to register and inspect private nursing homes. The promoters do not expect to carry their bill this session, but will seek to get a select committee appointed to consider the whole question.—*British Medical Journal.*

Mixed Tumors of the Salivary Glands.—Francis Carter Wood describes a group of extremely complicated tumors found in this region containing elements from both epi- and mesoblast. The structure of these tumors containing cartilage, bone, fat and lymphoid tissue and occasionally striated muscle is explained by the misplacement of mesoblasts. The structure of the parenchyma is not characteristic and its epithelial nature cn only be considered as probable. In about 24 per cent. epithelium is undoubtedly present. But there is never any indication of endothelium. The early embryonic disp'acement of epiblasts during the formation of the salivary glands and bronchial clefts may account for most of the peculiarities of the cells of these tumors, especially the lack of most of the typical features of epithelium. The same condition is found in the epithelial cells of congenital moles where the epithelium resembles connective tissue because it is undifferentiated and adherent to the stroma. The clinical course followed by these mixed tumors of the parotid and submaxillary glands is strikingly dissimilar to the true sarcomata and carcinomata, for one variety is always slow growing and very rarely malignant. The lymph glands in the neighborhood do not become involved, and consequently post-operative recurrences, when present, are localized in most cases.—*Annals of Surgery.*

Drainage in Surgery.—In cholecystotomy drainage is necessary; the so-called ideal cholecystotomy without drainage having too great mortality rate. In common-duct cases I still use the tube surrounded by gauze and rubber tissue. In cholecystectomy I feel safer to use a cigarette drain, because conditions are not so favorable to healing as in chronic appendicitis in which I never drain. In two cases of cholecystectomy within the past year drainage saved my patients' lives. In one of them the ligature on the cystic duct gave way, allowing a free escape of bile into the peritoneal cavity, and in the other an infection occurred at the same point.—JAMES E. MOORE, in *St. Paul Medical Journal.*

The Combination of Rubber and Cotton Gloves.—Goepel recommends the use of cotton gloves worn over those of rubber, and believes that this solves the question of hand disinfection. The rubber furnishes a complete barrier between skin and wound, while the cotton remedies two defects inherent to the rubber alone. It obviates the slipperiness of the wet rubber and, at the same time, entirely protects it from tearing. The double glove does not increase the difficulties of manipulation to any material extent, while, when palpation of a cavity or organ is necessary, the cotton glove may be temporarily slipped off, as such maneuvres do not place any demands on the strength of the rubber. Furthermore, with such protection against laceration, the surgeon's hands do not require very energetic sterilization and time and the surgeon's skin can both be saved.—*Centralblatt für Chirurgie.*

Pulmonary Hemorrhages.—Bozoky says that the patients who most frequently suffer from severe hemorrhages are not those in advanced stages of tuberculosis, but rather fairly vigorous individuals with early lesions and a powerful heart action that expels a large volume of blood through even a small opening in the eroded vessel. The symptoms described by patients as premonitory of hemorrhage will usually be found to have no foundation in fact, and the really serious hemorrhages occur without warning. The treatment consists in placing the patient with the chest somewhat raised and opening the clothing at the neck. A hypodermic injection of morphine is given and the patient encouraged to take long, deep breaths and cough as little as possible. In this way clotting is favored and freshly formed thrombi are not torn loose. The ice-bag and cracked ice internally are psychical measures, and ergot also has little value except in this way. The gelatin injections have shown themselves ineffectual, and are not free from danger.—*Zeitschrift für Tuberkulose und Heilstättenwesen*, Vol. 5, No. 3, 1904.

The Lymphatic Constitution.—W. H. Sheldon claims that this condition does actually exist, and explains certain obscure phenomena. The cases of sudden death in children without any previous illness come under this category. These deaths are more common in cities and on autopsy show a general enlargement of all the various lymphatic glandular tissues, also especially of the thymus gland. The author thinks that death is not due to the pressure of the large thymus, but to reflex paralysis of the heart, made possible by an abnormal irritability of the nervous system. The function of the ductless glands has to do with the regulation of general metabolism, blood-pressure, and serve in the higher organization of the blood. There is a relation between the thymus and marasmus, for atrophy of this gland is always found in infantile atrophy, and the condition of the thymus is an index of the general nutrition of infants. It is possible to draw an analogy between the relation of the diseased thyroid to myxœdematous conditions and the relation of the hyperplastic thymus and its coördinated lymphatic organs, to the symptom complex characterized by the general condition known as the "lymphatic constitution." This constitutional condition is important from a therapeutic, prognostic, and medicolegal point of view.—*Wisconsin Medical Journal.*

Abdominal Pain in Pleurisy and Pneumonia.—I. E Herrick, says that it is well known that pain may occur i regions distant from the seat of the pathological lesio and cases occur in which it is impossible to say at fir whether the trouble is abdominal or thoracic. Each ca must be judged on its merits, and operating or waitin cannot be decided by any hard and fast rule. In som doubtful cases with threatening abdominal symptoms, would be better to err on the side of operation than to l a possibly ruptured gall-bladder, appendix, stomach, intestine go untreated for six or twelve hours. An e ploratory incision might be made under local anæsthesi or nitrous oxide gas. The main safeguard is to think the possibility of a thoracic origin for the abdomin symptoms, and in the case of thoracic disease there w generally be found some thoracic pain or altered e pectoration and cough. Or again, the temperature ma rise too high and abruptly for abdominal disease. Th abdomen in these cases is often pseudo-tender. A ligh touch hurts, but quiet, steady, deep palpation with th flat hand does not increase the pain. At the beginning inspiration there is a yielding of the abdominal walls th is seldom seen in true peritonitis.—*Illinois Medical Journa*

The Germicidal Action of Alkaline Solutions—I. F Forrest and R. T. Hewlett arrive at the following co clusions: A one-per-cent. solution of sodium carbonate absolutely germicidal to B. typhosus and B. coli, and pa tially so for M. pyogenes aureus. A 0.06 per cent. sol tion of caustic soda in physiological salt solution has t same action. A 0.12 per cent. solution of potassiu hydroxide with 0.06 per cent. of sodium chloride is abs lutely germicidal for B. typhosus and B. coli and nea so for the M. pyogenes aureus. The following solutio has a similar action. Potassium hydroxide 1.2 gram sodium chloride 6.0 grams; sodium bicarbonate 1.0 gram di-sodium hydrogen phosphate 1.0 grams; and wate 1,000 c.c. This same solution with caustic soda subs tuted for caustic potash acts in a similar way. The solutions have an absolutely germicidal action upon th cholera vibrio. Weak ammoniacal solutions are also sim larly germicidal. The results obtained with anthrax a irregular, probably because of the difficulty of handling th organism. A solution of salts made to imitate the salts the blood serum was not germicidal. The germicid action of nucleins is not yet proven, the authors hol because the alkaline solutions used in their preparati would account for their apparent bactericidal power.—*Journal of the Royal Army Medical Corps.*

Bronchoscopy.—Arnold Schwyzer describes a case of bone lodged in a bronchus of the third order and it removal with the bronchoscope. Bronchoscopy is th most recent addition to direct examination of the trachea He does not think inferior bronchoscopy should be rel gated to the specialist. Straight tubes of different size and lengths are used, and the exploration of the air pas sages can be carried far beyond the bifurcation of th trachea. An electric head light can be used and a reflect ing mirror, through the center of which the end of the tub and exposed bronchi can be easily seen. The electric light can be fastened to the bronchoscopic tube or an ordinary light and head mirror may suffice, but are not so convenient. The bronchoscopic tubes are connected with a solid handle, with which considerable force can be applied to the tube in pushing it in the desired direction. In addition, guide tubes are used to facilitate changing the bronchoscope for a longer or shorter one of the same caliber; sponge holders, a fine suction tube, some hooks and several kinds of forceps constitute the armamentarium. The instruments are equally useful for œsophagoscopy. The examination can be done either directly through the mouth and larynx, requiring tubes up to fifteen inches in length, or through a tracheotomy wound; the latter is called inferior bronchoscopy. The head must be thrown as far back as possible to allow introduction of the tube in the axis of the body.—*Annals of Surgery.*

PROPOSED REMODELING OF THE ARMY MEDICAL SERVICE.

THE fact is too obvious to need much argument that in order to be a really efficient army medical officer, a thorough special training is requisite. This truth is strangely overlooked by many, who, although they recognize the necessity of the purely military officer undergoing years of arduous study to render him competent to perform his prospective duties, seem to imagine that, like the poet, the army medical man "*nascitur non fit*," and should by a process of intuition be able to fill his position without any experience whatever. The Spanish-American war and the Boer war both provided a rude awakening to those who held these views, for creditably as the civil surgeons who volunteered their services played their part, yet no one acquainted with the true circumstances but had to confess that the lack of trained army surgeons was bitterly felt and was not the least blot in the state of unpreparedness which marked the policy of the United States and Great Britain alike. The British Commission, appointed to investigate the care of the sick and wounded in the South-African campaign, found that the staff of officers and orderlies of the medical corps should be established on a scale sufficient to enable it to discharge adequately the duties cast upon it in times of peace and by the smaller wars. The large European continental nations—and especially Germany—have a system whereby civil surgeons, who, in the case of a great war, might be called upon to take the field, receive a certain amount of training in military duties, and although neither Great Britain nor the United States can be compared with regard to military affairs with the countries of Europe, it is nevertheless plain that their medical department should be in such a condition that it can fulfil its duties adequately in time of peace. Further than this, the medical department of an army, like other parts of it, should be organized with reference not exclusively to peace conditions, but with reference to efficiency in war. This principle has always been strangely neglected in the organization of the medical department of the United States Army, for while the army is at present officered for a strength of one hundred thousand men, the medical department is only officered for about forty-five thousand.

There are at present less than five hundred medical men, which number includes two hundred contract surgeons, performing the duties of medical officers of the army. It is believed that 450 regular officers will be sufficient for the ordinary duties of the medical department in time of peace, which force must be supplemented for special work by physicians from civil life, and in the event of war, or of "little wars," expeditions, epidemics, physicians from civil life must be still further called upon to expand the medical service.

In view of the inadequacy and inefficiency of the medical service of the United States Army under existing conditions, a bill has been introduced into the national Senate and House of Representatives, designed to remedy the defects of the present system.

The first section of this bill provides that the medical department of the United States Army shall consist of one surgeon-general, with the rank of brigadier-general; a medical corps and a medical reserve corps; and the hospital corps, the nurse corps and dental surgeons as now authorized by law. The second section provides that the army medical corps shall consist of 450 regular medical officers, and that satisfactory measures shall be taken as to recommissioning all officers of the medical department in active service, other than the surgeon-general, in the corresponding grades of the medical corps established by this act, in the order of their seniority and without loss of relative rank in the army. The third section provides that promotions in the medical corps to fill vacancies in the several grades created or caused by this act, or hereafter occurring, shall be made according to seniority, but all such promotions and all appointments to the grade of first lieutenant in said corps shall be subject to an examination, the provisions of which are stated after. The fourth section provides that no person shall receive an appointment as first lieutenant in the medical corps until he shall have successfully passed an examination, under regulations to be prescribed by the Secretary of War, before an army medical board consisting of not less than three officers of the medical corps. The fifth section provides that no officer of the medical corps shall be promoted therein until he shall have successfully passed an examination before an army medical board, consisting of not less than three officers of the medical corps, and that fair measures shall be taken in the case of failure in physical examination. The sixth section provides that nothing in the act shall be construed to legislate out of the service any officer now in the medical department of the army, nor to affect the relative rank for promotion of any medical officer now in the service, or who may be hereafter appointed therein. The seventh section provides that for the purpose of securing a reserve corps of medical officers available for military service the President of the United States is authorized to issue commissions as first lieutenants to such graduates of reputable schools of medicine, citizens of the United States, as shall, from time to time, upon examination, be prescribed by the Secretary of War, be found physically, mentally, and morally qualified to hold such commissions, the persons so commissioned to constitute and be known as the medical reserve corps. Regulations as to promotion and rank of said reserve corps are also stated. Section eight provides that in emergencies the Secretary of War may order officers of the medical reserve corps to active duty in the service of the United States in such numbers as the public interests may require, and may continue such officers on such duty so long as their services are necessary. Section nine

provides that officers of the medical reserve corps when called upon active duty shall be entitled to the pay and allowances of first lieutenants of the medical corps, but that no officer of this corps shall be entitled to retirement or retirement pay; nor shall he be entitled to pension except for physical disability incurred while on active duty and in line of duty.

The question of pay and promotion is a burning one with the army medical officer. When it is considered that owing to the extension of medical knowledge, due to the development of specialties and by a general advance in all branches of medical education, the cost of acquiring this knowledge has greatly increased, it must be recognized that the army medical service offers no correspondingly attractive inducements. Promotion, too, is slow and compares unfavorably in this respect with its sister service in Great Britain. The fact must also be borne in mind that while the education of the medical officer is expensive and long, his brother officer of the line receives a free education at West Point, and his years at that Academy are counted for increased service pay.

Indeed the army medical service is at present unpopular with the young members of the medical profession of this country. As a career it does not hold sufficient inducements to the clever and ambitious man. Contrary to the belief of many army officers, the medical department of the army is one of quite its most important branches, and it would be a mistake of incalculable magnitude if through injudicious treatment it were to be allowed to fall into disrepute and to lose the high character which, despite its defects, it has always maintained. It is evident, at any rate, that steps should be taken to better the present state of affairs, so far as the army medical service is concerned. The present bill is perhaps defective in some points, but on the whole it is sound in principle. The care of soldiers should be placed in the hands of properly and specially trained medical officers. At the same time surgeons from civil life who join the reserve should be treated generously, possibly more so than is proposed in the pending bill. The contract surgeons now serving in the army should also be used with every consideration, for it must not be forgotten that unless civil surgeons are convinced that generous and just treatment will be meted to them, there will be great difficulty in filling the ranks of the suggested civil reserve force.

HEALTH CONDITIONS OF COLON AND VICINITY.

Surgeon J. C. Perry of the Public Health and Marine Hospital Service has reported to the Surgeon-General of that service concerning the diseases which are prevalent in Colon and in the Isthmus of Panama district generally. The statistics from which the information is gathered are compiled from the records of the Panama Railroad Hospital and the French Hospital, and show the prevailing diseases, nationalities affected, and the mortality in such cases.

The following points are considered by the writer: (1) To what extent does malarial fever prevail; (2) The types of this disease; (3) To what extent do the pernicious forms prevail and what types; (4) Do the Panamaans and negroes enjoy an appreciable immunity to malarial fever; (5) To what extent does yellow fever occur; (6) The number of cases of dysentery; (7) Other diseases and their frequency; (8) The approximate morbidity based on hospital statistics; (9) Mortality; (10) Effects of sickness on wage-earners and consequent financial loss; (11) To what extent can the prevailing diseases be diminished or prevented by proper sanitary equipment and regulations.

These are the conclusions reached by Dr. Perry. A study of the hospital statistics shows that malarial fever is a common disease in Colon as well as in other places on the Isthmus. Physicians connected with hospitals state that at least 75 per cent. of all diseases occurring in Colon are malarial fever. The type of malarial fever is difficult to determine from the records, as the diagnosis given is simply that of malarial fever.

Figures, from the Panama Hospital, however, tend to show that most of the fever was of the remittent type. From a consideration of the statistics, observation of the cases of malarial fever in the hospitals and from information derived from the physicians of the town, it appears that only about 12 per cent. of the malarial fevers occurring in Colon are of the estivo-autumnal form.

Regarding pernicious malarial fever, while it is difficult to make specific statements, it does not appear to be prevalent among the present population. The writer does not believe that it prevails to the extent generally assumed.

Again, Dr. Perry, judging from hospital statistics, is of the view that the negro resident of Colon does not enjoy any great degree of immunity against malarial fever. The fact must be borne in mind when discussing immunity against malarial fever that the resident population is referred to—one protected to a certain extent by previous attacks, the habit of taking quinine as a prophylactic and by observing the rules that experience has taught them to be effective. Even under these conditions the disease is fearfully prevalent. Therefore, when fresh material is introduced, it is easy to predict that the result will be a much larger percentage of sufferers among the new arrivals, with increase in the virulence of the disease unless the newcomers are under careful supervision and have the benefits of improved sanitary conditions. An examination of the tables show that malarial fever is most prevalent during the months of May, June, July, and August.

As to the extent to which yellow fever occurs, the writer does not place much faith in available statistics for finding out this point, for the reason that the disease is not reported as such. Nevertheless, he is of the opinion, although admitting that little yellow fever may occur in Colon, the infection is present and only an influx of a non-immune population is needed for the disease to assume epidemic proportions.

There seems little doubt that both the amœbic and bacillary forms of dysentery exist.

Tuberculosis is common among the negroes, and rheumatism is recorded as of frequent occurrence. Some cases of pneumonia occur and are generally fatal.

Anæmia is common, but probably most of the cases are secondary to malarial infection; uncinariasis is no doubt present. Ulcers are common affections; some are syphilitic, but the majority of cases result

ı abrasions or the bites of insects, scratching and ction of the wound.

r. Perry estimates the annual morbidity at 1,960, bout one-third of the entire population. The an- l death rate of Colon is estimated by the author ot less than 50 per 1,000. He also considers that ng the natives, assuming that about 2,000 cases ickness occur annually, 75 per cent. of which due to malarial fever, and estimating the length me each case is under treatment or incapacitated n days, there would be a loss of 15,000 days an- lly, which would mean a pecuniary loss of $11,-

In a new population the loss would doubtless roportionately greater, owing to the marked in- se in sickness.

ı answer to the question, To what extent can the railing diseases be diminished or prevented by per sanitary equipment and regulations? Dr. ry has this to say, "Having shown that 75 per t. of the diseases are malarial; that yellow fever ts and will increase upon the introduction of new erial; that dysentery, tuberculosis, and rheuma- n are common, I think a conservative estimate ld be that 80 per cent., or even more, of these di- es could be prevented."

he United States Government will undertake the ing of an Isthmian Canal well knowing of the ace to life and health of the workers thereon that carrying out of such a project will entail. By ful supervision and by conducting proper sani- arrangements the risk to life can be greatly de- sed. It is obvious then that no expense or ble should be spared to render the conditions in about Panama as salubrious as possible. If this not done, and the building of the canal be at- ded by great loss of life, a slur cannot but be at- ed to the responsible authorities. Timely warn- has been given to which prompt attention should aid.

FORCED SLEEP.

ILE all the factors underlying sleep have not as been adequately elucidated, the immense physi- ical importance of the phenomenon has long n appreciated by physicians, and the relief from strain of conscious being and the reinvigoration ruing from it have flavored the meditations of ilosophers and exalted the song of the poets.

And so, while the experience of mankind has justi- the appreciation, it has remained for the phy- an practically to apply that experience in the nagement of disease. The fact that in many nctional disorders of the nervous system insomnia an important symptom, and that, furthermore, the jority of mental affections are heralded by sleep- ness, were, indeed, enough to rivet the attention practitioners. Moreover, the benefits accruing such cases through attacking the disorder of sleep ere sufficiently striking to cause the most searching hysiological and pathological investigations re- rding the function itself. From these studies here issued, at length, the conviction that, by in- reasing the duration and improving the quality of leep, much good might be wrought in affections of the nervous system, particularly those characterized by great exhaustion or irritability or both. This, in few words, is the genesis of the so-called "Sleeping Cure," which, as stated in a recent editorial in the *New York Tribune*, is now winning high favor abroad, and particularly in London. As justly observed by the *Tribune*, however, this mode of treatment is to the practitioners of the United States no novelty.

As long ago as 1883 Dr. J. Leonard Corning of this city brought forward this plan of managing functional nervous disorders in a monograph entitled "Brain Rest, a Disquisition on the Curative Properties of Prolonged Sleep," and in a subsequent edition published in 1885 the whole matter of practical management was elaborated to the last detail. On page 66 of this classical little monograph Dr. Corning observes that "As applied to the brain, rest implies something totally different from that which is described by the term when used in connection with the muscle, joint, or spinal cord. This radical difference is chiefly owing to the fact that the brain being the organ of the intellectual processes, rest, in so far as it concerns that organ, means nothing less than a cessation of mentalization, with all thereby implied. It is impossible by a mere fiat of the will to cause cessation of thought; the very idea embodies a contradiction, for the will as physiologically understood is itself a product of very complicated intellection and cannot therefore be regarded as a thin *sui generis*—assom ething without the pale of other psychical processes." Only during sleep is the ideal repose of the cerebral faculties realized. But, while a physiological amount of sleep is sufficient to achieve this in health, the period of unconscious repose must be greatly augmented when by overtaxation or inordinate mental strain the nerve-cell has become devitalized and is no longer able to hoard up a sufficient store of energy during the usual period of unconsciousness. It is in such cases that prolonged sleep, a sleep continued for ten, fifteen, or even twenty, hours at a time, achieves the most striking results.

"As a rule," observes Dr. Corning, "I am in the habit of secluding the subject in a darkened room, eventually for from ten to fifteen hours at a time, according to the amount of sleep it is desired should be had during the twenty-four hours. I do not, however, attempt great things in the way of sleep at first; but, on the contrary, the duration of the period of unconsciousness is progressively increased by the utilization of habit, hydrotherapy, appropriate food and, in urgent cases, moderate medication." In extreme cases the period of sleep is prolonged to as much as twenty hours at a time, the patient being awakened and given small quantities of nourishment and then allowed to sleep aga n.

He warns, moreover, against the evils accruing from attempts to keep in bed nervous, irritable persons while in a conscious condition. Such individuals should be told to lie down only on the appearance of drowsiness, which, in intractable cases, may be brought on by the moderate use of sedatives during the latter part of the day, and exceptionally by the exhibition of hypnotics before retiring. Recumbency, then, is purely incidental, the prolonged unconsciousness is all.

In thus strenuously insisting on the radical difference between cerebral and ordinary corporeal rest, Dr. Corning has rendered a substantial and practical service.

Space does not permit, however, of more than a brief synopsis of a plan of treatment which, so far

as originality attaches to it, was developed in this country and systematically practised over twenty years ago.

Differential Diagnosis of Typhoid Fever.

In the *Journal of the Association of Military Surgeons* is now being published the Enno Sander Prize Essay, 1903. The essay is by Major Frederick Smith of the British Royal Army Medical Corps, and deals with the differential diagnosis of typhoid fever in its earliest stages. The March issue of that journal treats of the differential diagnosis of malarial fever and typhoid fever. The writer points out that these two diseases are often mistaken the one for the other, and that it is the continued or so-called remittent forms of malarial infection that give rise to this error. "As a matter of fact," says Major Smith, "it is not very many years ago that nearly all the enteric fever in India was called malarial fever." It was thought, too, and is still believed by some, that a sort of hybrid between malarial and typhoid fever exists in the tropics. This was known as "typho-malarial fever."

The author declares that from a somewhat extensive acquaintance with malaria and enteric, the diagnosis to him is often very difficult and only mere guess-work. Microscopical examination of the blood, even if entirely satisfactory, frequently cannot be properly carried out when soldiering.

The most difficult cases, according to Major Smith, are the so-called bilious remittents. "In these," he says, "the temperature is often low, there is diarrhœa (the stools may be dark, but we find that not infrequently in tropical typhoid during the first week), vomiting, foul tongue, etc. An experienced man will generally make a correct diagnosis, but the best of us may fail to do so at once. . . . My own experience is that the best way to settle the question is to treat a doubtful case promptly as malaria. If calomel, quinine, etc., judiciously administered by experienced hands, do not cure the fever in four days, or at any rate bring about marked improvement, the case is, in nine cases out of ten, not malaria at all. In most of the few purely malarial cases which resist this treatment the patient is going to die."

The general conclusions drawn by Major Smith with regard to the differential diagnosis (on clinical grounds alone) of typhoid fever in the earliest stages are as follows: (1) That the diagnosis of typhoid fever in the earliest stages of the disease presents probably greater difficulties than that of any specific infectious ailment. (2) That there is scarcely any disease accompanied by fever which has not been at times mistaken for typhoid fever. (3) That a good many cases are wrongly diagnosed owing to mere carelessness or to want of knowledge. (4) That the disorders most liable to be confounded with typhoid fever are—typhus fever, tuberculosis, pneumonia, influenza, febricula, or unnamed continued fever, Malta fever, malarial fever, and paratyphoid. (5) That it is frequently impossible by non-bacteriological methods to differentiate between typhoid fever and the diseases named above in four days or even a week and more. (6) That our safety from a public health point of view lies in regarding all doubtful cases as typhoid until they have been proved to be something else. (7) That the anomalous cases are more numerous, and the difficulties in the way of diagnosis greater, in military than in civil life.

University of Pennsylvania.—Dr. James K. Young has been appointed assistant professor of orthopedic surgery, and chief of the orthopedic section of the University Hospital.

Bacteriology as Applied to the Examination of Shell-fish.

It has been stated ofttimes of late that shell-fish spread typhoid fever very frequently; in fact, that shell-fish play an important part in the dissemination of the disease. Proof, too, has been forthcoming from many quarters that such is indeed the case, and the striking evidence to this effect which has been brought forward cannot be disregarded. According to the *British Medical Journal*, February 13, the British Royal Commission on Sewage Disposal has recently handed in its report, a part of which is taken up by conclusions as to bacteriology applied to the examination of shell-fish. Dr. Klein stated before this commission that he had not found that the normal oyster harbored within its shell or within its body the bacillus coli communis or other bacillus closely allied to it, and that he regarded the presence of the bacillus coli as indicating sewage contamination when found "in considerable numbers of oysters in a series of samples from a particular locality." The commission instructed Dr. Houston to investigate the premises on which Dr. Klein's conclusions were based. Dr. Houston examined over one thousand oysters, some from the purest waters in which oysters are grown or fattened in Great Britain, and some from layings, etc., obviously liable to pollution. The results showed that nearly all the oysters so examined, from whatever layings they were taken, contained bacillus coli communis or other bacillus coli closely allied to it. The results as to deep-sea oysters were not quite decisive, but "pointed strongly to the conclusion that not only the typhoid bacillus, but even bacilli resembling this or the colon bacillus were absent from them."

The whole matter was summed up by the commission as follows: "We accept the view that, for the present, results of bacteriological examination must be interpreted in the light of topographical observations. As a corollary, it would seem that the bacteriologist can at present do little more than urge that results he is obtaining point to the need of a further and more careful examination of local conditions of the shell-fish or water samples submitted to him; that for the present topographical observations must determine whether any laying or portion is or is not to be considered free from risk of objectionable contamination." The commission also express the opinion that the mere presence of bacillus coli in an oyster does not constitute a justification for the wholesale condemnation of oysters; and that, furthermore, a single examination of a chance sample of oysters may be most misleading. Generally speaking, comparative examination of samples of water from the different layings gave results similar to those furnished by the oysters from the same layings, except that the water was generally purer than the oysters themselves, the oysters seeming to collect and retain within their shells these microorganisms. The evidence in support of the contention that shell-fish are important factors in the conveyance of typhoid is too weighty to be overcome. Although perhaps the presence of the bacillus coli does not justify the wholesale condemnation of oysters, yet, on the other hand, so many epidemics of typhoid fever have been traced to shell-fish, that it is better to destroy any members of this family open to suspicion rather than to run the risk of spreading the infection.

A Forecast of Radium in Fiction.

To the late novelist Lord Lytton is attributed the forecast of the discovery of radium. In his marvelous imaginative work "The Coming Race," in many respects the most remarkable of his writings,

novelist gave an account of the life led by a race uman beings far down in the bowels of the earth. distinctive feature of the book, in fact the ot upon which the plot hinges, is the possession these underground dwellers of a mysterious stance named vril, and which, as described by tton, is, according to Hornblow, writing in *The tic* for March, identical with radium. There is space in these pages, nor is it needful to enter utely into the matter, but the aforesaid writer nmarizes the similarities between radium and substance hatched in the brain of the author follows: "(1) Lytton says a small amount of could destroy a city as large as London, and t a child could destroy an army by merely ting at it a staff charged with the substance; nce assures us to-day that the power of radium almost limitless, that two pounds of it could troy three millions of people and that one ounce ld blow up a battle ship. (2) Lytton's subranean race lighted their streets with vril. nce tells us that radium gives out light and heat hout waste or diminution. It is, therefore, only question of quantity and proper adaptation, en the world will use radium for lighting purposes. This wonderful vril of the novelist could, he med, cure diseases. Indeed, the race depended olly on it to restore or invigorate life. Experints recently made with radium in hospitals monstrate that it will cure certain forms of ease, such as lupus and other skin diseases. is also believed that it will cure cancer; on the er hand, if applied differently, it will burn the and destroy life. Physicians declare that air dered radioactive will cure consumption, and at water rendered radioactive will relieve stomach ubles."

Could then, asks Hornblow, Lytton have been herwise than inspired when he wrote half a tury ago of vril: "It enables the physical organiza n to reëstablish the equilibrium of its natural wers and thereby to cure itself."

The writer in *The Critic* has taken the exaggerated ews of the properties of radium, so widely disminated by a portion of the lay press and by a rtain number of the medical profession. The uth is that the properties of radium are not yet finitely known. It may be that its limits have t been gauged and that its powers are even eater than its most ardent advocates believe. ut at present we are somewhat in a state of spectancy with regard to radium. True, what known of the substance is wonderful enough, and is to be hoped that the glowing anticipations rmed in the minds of some of its eulogists as to s potency may be fully realized, and that Lytton's onderful vril may be equalled by radium.

Dr. William Pepper.

A life of the late Dr. William Pepper of Philadelphia has recently been published which provides an object lesson to medical men and to men of ideas generally. Mr. Thorpe's life of Dr. Pepper cannot but intensify the feeling of admiration universally felt by Americans and also by Englishmen for that great man. Dr. Pepper's sole aim in life was the advance of education. To this end he labored incessantly, and although in his later years afflicted with an incurable and most painful malady, he still endeavored to carry out his views. He was provost of the University of Pennsylvania, and the writer of many important medical works, and conducting an extensive practice, but at the same time he pursued his plans for the advancement of his fellow man.

Mr. Thorpe tells of the work Dr. Pepper had done by the time he had reached fifty:

Institutions founded, the University Hospital, the Commercial Museums, and the Philadelphia Free Library; institutions reorganized and re-treated, the University of Pennsylvania; public reforms, the improvement of the city's water supply and an entire change in the attitude of the public mind toward education and the ideals of life. To carry out these plans Dr. Pepper raised above $10,000,000 and secured about 100 acres of land from the municipality, lying near the heart of Philadelphia. To the execution of this task he gave the service of one of the most acute and, at the same time, the most practical minds ever vouchsafed to man. To this service of his genius he added the personal gift of $500,000, which he earned in the practice of an exacting profession. It may be doubted whether any other American has run a like career.

When the fact is borne in mind that Dr. Pepper died at the age of fifty-three, it seems almost incredible that he should have crowded into so short a life the amount of solid endurable work that he did. He undertook no project which he did not carry to a successful issue, and as Mr. Thorpe says "His love of work and ceaseless activity were a disease incurable, but encouraged by more activity." He had a very large practice, but "his gratuitous practice was equal to the entire practice of many a well-established physician, and on no occasion was he known to refuse his aid because the patient was poor."

The noble deeds of William Pepper add lustre to the whole profession of medicine in America, for like Virchow he was not only foremost in medicine but was also a most admirable citizen and public-spirited man. His works are his monument, more enduring than brass, and the history of his life will call attention to the good that he has wrought, and act as an incentive to others.

News of the Week.

The Visit of Professor Ehrlich to Deliver the Herter Lectures at Johns Hopkins Hospital.—Professor Ehrlich, who is the director of the Institute for Experimental Therapeutics in Frankfort a. M., Germany, was invited by the University of Chicago to deliver an address on immunity on the 18th of March, and was honored with the degree of L.L.D. from that institution. He was also entertained by the University of Ann Arbor, and on his way to New York by the members of the Medical Faculty of the University of Buffalo. On the 1st and 2d of April he was the guest of the Association of American Pathologists and Bacteriologists, which held its annual meeting in New York, and delivered an address on the therapeutics of trypanosomiasis on the basis of experiments carried out by Shiga and himself.

On April 12, 13, and 14 Ehrlich will deliver the Herter Lectures at the Johns Hopkins University (in McCoy Hall, 4.30 P.M.). The subjects will be: (1) "The Mutual Relations between Toxin and Antitoxin;" (2) "Physical Chemistry versus Biology in the Doctrines of Immunity;" (3) "Cytoxin and Cytotoxic Immunity." The lectures will be delivered in the German language. On April 18 a banquet will be tendered to him by the German Medical Society of the City of New York. On the 19th he will be the guest of the Harvard Medical School. He sails for Europe on the 26th. He is accompanied by wife and daughter.

Mortality in February in New York State Greatest on Record.—The bulletin of the New York State Department of Health for the month of February

shows that there were 12,749 deaths in the State during that period, or an average of about 440 deaths a day. The bulletin goes on to say that this number exceeds by almost 2,000 the average for the month during the past five years. Pneumonia was the chief cause of the increase, there being 1,800 deaths from that disease.

Gift to Eye Infirmary.—Mrs. John E. Parsons, daughter of the late Benjamin H. Field, ex-president of the New York Eye and Ear Infirmary, has sent $1,000 to go toward a fund to be used for the perpetual endowment of the institution.

Anti-canteen Victory.—The House of Representatives, on March 31, adopted an amendment to the Sundry Civil Appropriation bill, providing that no appropriation should be made to any State or Territorial home for soldiers that maintains a bar or canteen at which intoxicating liquors are sold.

Verdict against Dr. Conrad.—Dr. Edward E. Conrad of 127 West Forty-seventh Street was found guilty on March 31, by a jury in Part II of the Court of General Sessions, of having attempted to perform a criminal operation.

The Santa Barbara County Medical Society and the Army Medical Bill.—At a meeting of the Santa Barbara County Medical Society, held on March 15, a resolution was adopted with regard to the Army Medical bill now pending before Congress. On the whole the resolution commended the bill, but exception was taken to the last five lines of Section 9, which reads as follows: "*Provided*, That no officer of the Medical Reserve Corps shall be entitled to retirement or retirement pay; nor shall he be entitled to pension except for physical disability incurred while on active duty and in line of duty."

The gist of the argument brought forward by the Santa Barbara Society was that the enactment of such a regulation makes it harder on an officer of the Medical Reserve Corps than on a private soldier, who, as the law stands to-day, is entitled to pension for disability from disease or accident after he leaves the service if it interferes with his gaining his livelihood by manual labor. The society thinks that the discrimination made between officers of the Medical Corps and officers of the Army Medical Reserve Corps is unjust and request their Senators and Representatives in Congress to use all their influence to have the last five lines of Section 9 omitted and an amendment inserted that these officers be treated in this respect as are the officers of the Army Medical Corps.

Summer Home for City Children.—Dr. Edward Martin, Director of Public Health and Charities of the city of Philadelphia, has purchased, at his own expense, a mansion and twenty acres of grass and woodland on the banks of Crum Creek in Delaware County, Pennsylvania, for the purpose of providing a place where ill-treated, poorly fed and sickly children can, during the summer, obtain fresh air and good food and spend a life in the open.

Hygienic Talks to Mothers.—Arrangements are being made to continue the health-talks to mothers inaugurated by the Philadelphia Department of Health and Charities last summer. A number of physicians have volunteered to deliver lectures in different parts of the city under the auspices of various charitable organizations.

The Late Dr. Aimée Raymond Schroeder.—The following preamble and resolutions were adopted at a recent meeting of the Women's Medical Association of New York City:

"Aimée Raymond Schroeder, M.D., died in New York City on December 25, 1903, eight days after an operation for appendicitis. She was the youngest daughter of the late Henry J. Raymond, founder of the *New York Times*, who was a strong supporter of the Doctors Elizabeth and Emily Blackwell in their early struggles for the medical education of women.

"Dr. Schroeder was born in Montreux, Switzerland, August 21, 1857. Many years of her youth were spent in Europe, and she then acquired that proficiency in music and modern languages for which she was so well known in after life. After graduating from the Women's Medical College of the New York Infirmary in the class of 1889, she served in the out-practice and dispensary, but retired from active practice upon her marriage in 1893, and thereafter devoted herself to literary medicine. She translated and revised various medical works, wrote the foreign abstracts in the pediatric department of the *Journal of Obstetrics* for some years, and at the time of her death was a valued member of the editorial staff of the MEDICAL RECORD.

"Dr. Schroeder showed a constant interest in the medical education of women. She was indefatigable as secretary of the Association for the Advancement of the Medical Education of Women, and was always an active worker for the Infirmary.

"The grace and charm of a woman of broad culture and rare accomplishments brought her the admiration of many friends; while her generosity, her kindness, her perfect truth and loyalty, the attributes of her noble personality, endeared her to an even wider circle. Therefore,

"*Resolved*, That in the death of Dr. Aimée Raymond Schroeder this association and the medical profession have lost a beloved and honored member, and

Resolved, That this be spread upon the minutes, sent to the family, and published in the city medical journals."

"*Committee:* { MARTHA WOLLSTEIN, MARY PUTNAM JACOBI, ELIZABETH STOW BROWN.

Dr. Wm. Duffield Robinson of Philadelphia has been, without assigned reason, removed by Governor Pennypacker as a member of the Board of Inspectors of the Eastern Penitentiary. Political influences are believed to underlie the removal. Dr. Robinson has been particularly active in investigating and exposing abuses in the management of the Penitentiary in which he was for several years resident physician. His work in the Board of Inspectors was only recently commended by the Governor.

Death Rate on the Isthmus of Panama.—According to the New York *Sun*, April 3, a high death rate prevails at present on the Isthmus of Panama, and in the opinion of the Marine Hospital Service, whose surgeons are stationed at Colon and Panama, the medical officers connected with the Isthmian Canal Commission have a large task before them. Official reports from both sides of the Isthmus show that there were many cases of death from several causes during the week ending March 13. In Panama, where there is a population of about 18,000, there were thirty-one deaths during the week. This is equivalent to an annual death rate of about 90 per 1000 of population. The annual death rate of Colon for the same period figures out at 52 per 1000. No one died, so far as was reported, of yellow fever, but there was a high mortality from other fevers and from tuberculosis.

The Kaiser's Condition.—The lay journals of New York for April 3, have all something to say concerning the Kaiser's health. A special cable to the *New York Times* reported as follows: While foreign newspaper reports of the condition of the Kaiser's health

are exaggerated, they have a basis of truth. It is learned from a reliable source that leading medical authorities differ as to just what is the matter with him, but in order to check any possible existing inherited tendencies advised his present trip. The health of three other German monarchs, the Prince Regent of Bavaria, the Grand Duke of Baden, and the King of Saxony, also causes concern.

Columbia Medical Changes.—The announcement of the College of Physicians and Surgeons, the Medical School of Columbia University, has just been issued for the coming year, 1904–1905. Two new names appear among the officers of instruction—Dr. Harry McMahon Painter, Professor of Clinical Obstetrics, and Dr. Gorham Bacon, Clinical Professor of Otology. Four new names have been added to the Faculty of Medicine—Profs. Joseph A. Blake, Samuel W. Lambert, William J. Gies, and Harry McM. Painter. The most important change to be made next year will be in the increase of the tuition fee from $200 to $250, and at the same time in the establishment of fourteen scholarships available to all students, and of an annual value of $250 each. —*New York Times.*

Changes in Stations of Medical Officers of the Army.—The following officers of the Medical Department who recently completed a course of instruction at the Army Medical School in Washington, have been assigned to stations: First Lieut. Jay R. Shook, to Fort Leavenworth, Kan., relieving First Lieut. Ralph S. Porter, assigned to Fort Niobrara, Neb.; First Lieut. Reuben B. Miller, to Fort Screven, Ga., relieving First Lieut. Harry L. Gilchrist, assigned to the General Hospital, Washington Barracks; First Lieut. F. Juenemann, to Fort Ringold, Tex.; First Lieut. Edgar W. Miller, to Fort Clark, Tex.; First Lieut. William H. Tefft, to Fort Snelling, Minn., to relieve Capt. George A. Skinner, ordered to Fort Harrison, Mont., relieving Capt. George J. Newgarden, ordered to the Philippines; First Lieut. Robert E. Noble, to General Hospital, Washington Barracks; First Lieut. G. McD. Van Poole, to Fort Stevens, Ore.; James I. Mabee, to Fort Casey, Wash.; Percy L. Jones, to Fort Monroe, Va.; F. W. Palmer, to Jefferson Barracks, Mo.; John R. Bosley, to Fort Thomas, Ky.; Chester J. Stedman, to Columbus Barracks, Ohio; Joseph L. Siler, to Fort Logan, Col.; Capt. L. P. Williamson, from New Haven to St. Louis; First Lieut. W. De Witt, from New Haven to St. Louis.

The College of Physicians of Philadelphia at a largely attended special meeting held on March 30, decided by a large majority to remove from its present location at Thirteenth and Locust streets, to the site already purchased at Twenty-second and Ludlow streets, for $77,000. It is proposed to erect a modern and commodious building at a cost that may reach $250,000, a part of which sum will be obtained from the sale (for $175,000 or more) of the present building, which has been occupied for about a quarter of a century.

Transformation of Consumptive Hospital.—The Board of County Commissioners of Cook County, Ill., has authorized the transformation of the old consumptive hospital at Dunning into one for the sick insane, at a cost estimated at $10,000

The American Neurological Association has fixed the time of its meeting at St. Louis for September 15, 16, and 17. This will be immediately followed by the sessions of the various medical departments of the Congress of Arts and Sciences, beginning September 19.

Vital Statistics of Philadelphia.—Typhoid fever still prevails to an undue degree in Philadelphia, 321 new cases and 24 deaths having been reported for the week ended April 2, as compared with 148 new cases and 17 deaths for the preceding week. There were reported also 92 cases of scarlet fever and 7 deaths; 67 cases of diphtheria and 8 deaths; and 32 cases of smallpox and 7 deaths. The total number of deaths for the week was 588, as compared with 585 for the preceding week and with 535 for the corresponding week of 1903. The causes contributing to the largest number of deaths were as follows: Pulmonary tuberculosis 74, heart-disease 64, pneumonia 61, nephritis 36.

Obituary Notes.—Dr. James Brownlee Sanford, Speaker of the House of Representatives of Colorado, died in Denver, Col., March 16, 1904, from the effects of an operation for appendicitis, in the thirty-fifth year of his age. Dr. Sanford's career presented some remarkable features. He graduated from the medical department of the Baltimore University. After graduating he passed the State board examination in New York and received its license. In the fall of 1900 he located in Castle Rock, Col., and very quickly developed a large practice, and he was highly successful both in medicine and surgery. In the following January he was appointed county physician and health officer. In the fall of 1902 he was elected a member of the Colorado House of Representatives, and on organization of the House he was chosen speaker and discharged the duties of that position with such credit that he received at the close of the session a unanimous vote of thanks. But his great work in the Legislature was his medical bill, which provided for an efficient State board of examiners and that no one should practise medicine in the State unless he is a graduate of a recognized chartered medical college, or shall have passed the State board examinations. It was provided that the State board could refuse to grant or could revoke a license for fraud in examinations, for unprofessional conduct, such as aiding in producing criminal abortion, for obtaining a fee for assurance to cure a manifestly incurable disease, for advertising medicine or means whereby monthly periods of women may be reëstablished, or for publishing advertisements relative to diseases of the sexual organs, tending to injure the morals of the public. A person was to be regarded as practising medicine when he attached to his name a medical degree, or styles himself "Doctor" or "Surgeon" in a medical sense, or advertises to perform the duties of a physician. The penalty for practising medicine without such license was both fine and imprisonment. The bill met with determined and bitter opposition, but Doctor Sanford fought out the battle successfully and his bill passed both houses with but few dissenting votes. Such pressure, however, was brought to bear upon the Governor, by interested parties, that he failed to sign the bill. The State and County medical societies passed resolutions of strong approval and the deepest regret when his death was announced. At the time of his death he was secretary of the State Medical Legislative League, and also of the National Medical Legislative Council, the last meeting of which was recently held in Washington, D. C., at which meeting he was one of the two State delegates.

Dr. George H. Hammond, who had practised as a physician at Freeport, L. I., since 1872, died of pneumonia in that town on March 29. Dr. Hammond was born in 1846, and was graduated from Wesleyan and later from the medical department of New York University. Dr. Hammond who was married three

times, has a widow and two sons survive him. The deceased was a prominent Freemason.

Dr. GEORGE H. BULLER died on March 28, in the sixty-second year of his age, at his residence, 964 Fifth Avenue, New York. He was graduated from the Bellevue Medical College in 1869. He was a member of the Medical Society of the County of New York, the New York Physicians' Mutual Aid Association, the New York Academy of Medicine, and the New York Chemists' Association.

Dr. A. B. ARNOLD, for many years well known in Baltimore, died recently at San Francisco. He was graduated in medicine at Jefferson College and was professor of nervous diseases at the Baltimore College of Physicians and Surgeons from 1876 to 1898, when he left Baltimore for California. He contributed largely to medical and literary magazines.

Dr. JOHN GILWEE died suddenly at his home in St. Louis, on March 23, of heart failure. He was sitting at his desk writing out a death certificate when he was attacked and died in a few minutes. He was born at Farnham, Canada, sixty-nine years ago, but at an early age removed to Bloomington, Ill. The deceased was graduated in medicine from the St. Louis Medical College in 1877, and practised his profession for over a quarter of a century in the city of St. Louis. Dr. Gilwee made a provision in his will setting aside $2,000 for the care of his horse Tony which he had driven for twenty-three years.

Dr. STEPHEN P. TRUAX of Brooklyn, while performing an operation in the Brunswick Central Hospital in Brooklyn, on March 31, died suddenly of heart disease. Dr. Truax was born in Oswego and was graduated from the Long Island College Hospital in 1891. He was the visiting gynecologist of the Bushwick Central and a lecturer on obstetrics and gynecology in the Post-Graduate Hospital. The deceased had been affected with heart disease for some time and had recently been a sufferer from grip. Dr. Truax belonged to the Kings County Medical Society and to several Masonic organizations.

Dr. WALTER BURROWS, seventy-five years of age, a retired physician, died in April 2, at his residence, 138 Shilton Street, Newark. He was a son of the Rev. Dr. Burrows, en eminent Methodist clergyman, and was a graduate of Dickinson College and of the College of Physicians and Surgeons of New York City. A widow and three sons survive him.

Dr. WASHINGTON H. BAKER died in Philadelphia on April 1 at the age of fifty-seven years. He was a lineal descendant of George Emlen, who came over from England with William Penn. He was a great great grandson of George Ross, a signer of the Declaration of Independence. He was a graduate of Lehigh University and of the Medical Department of the University of Pennsylvania. He became later a resident physician in the German Hospital and then an assistant to Professor Penrose in the University of Pennsylvania. He was a visiting physician to St. Joseph's Hospital and surgeon to the Second Regiment N. G. P. He was also a trustee of Lehigh University.

Dr. CLINTON MUNSON, a retired physician of Tacoma, Wash., died at San Francisco on March 20, at the age of sixty.

Dr A. STANLEY DOLAN, until recently Assistant Superintendent of the Southern California Hospital for the Insane, at Highlands, died at Riverside on March 22, as a result of heart disease.

Dr. GEORGE IVINS, a native of New Jersey, but for the last twenty-five years a resident of Los Angeles, Cal., died at San Jose on March 24, at the age of sixty-four.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HOSPITAL MEETINGS AND FUNDS—IRISH GRADUATES' ASSOCIATION—PROPOSED SCHOOL FOR DISTRICT MIDWIVES—THE CARDIAC DULNESS IN CANCER—PROPERITONEAL HERNIA—INFANTILISM—FOREIGN BODIES IN THE AIR PASSAGE—ANTIVACCINATIONISTS—SIR L. BRUNTON—S. WILKS—OBITUARY NOTES.

LONDON, March 18, 1904.

THE Mansion House meeting on behalf of Kings College Hospital was held last Friday and may be considered a successful. The sum estimated to be necessary for the new hospital is £300,000 and the treasurer was able to announce that £106,762 had been subscribed. A telegram arrived at the meeting promising to deliver 50,000 bricks on the site of the new hospital "as a thank-offering for in-[illegible] attention forty-five years ago."

On Tuesday, at the Mansion House, the Lord Mayor presided over the annual meeting of the East London Nursing Society which has twenty-seven nurses working thirty-four parishes among the poor, and whose work has been reported as "very satisfactory" by the Inspector of Queen Victoria's Jubilee Institute. The report stated that 4,652 cases had been nursed during the year, and 1,[illegible] removed to hospitals. The work of this society deserves to be more generally known. When it is understood that it is in the poorest neighborhoods that the society works among the sick, the few hundreds required to meet necessities will be forthcoming.

On Wednesday the Lord Mayor presided at the annual meeting of the Royal Hospital for Chest Diseases. The income had fallen during the year and a great struggle has been necessary to keep all the wards open. The year commenced with a debt of £1,200 and now £1,3[illegible] owing to tradesmen. The Lord Mayor regretted that so valuable and old a charity should be in such low water especially at this unpropitious time for appealing when three great hospitals are asking for a million. Sir T. De la Rue, the chairman of the committee, said unless money was forthcoming for immediate debts, one of the wards must be closed. The large appeals to which the Lord Mayor had referred seriously affected the smaller hospitals in which equally good work was done, though it did not strike the public eye so forcibly.

This lament is being made in many directions, and I have hinted to you on former occasions, the partiality the funds is in some cases called in question. The trouble appears to be that they have laid down certain rules of distribution which are exceedingly rigid, whereas some elasticity is required to do justice all round. Another annual meeting held this week—that of the South London Ophthalmic Hospital—affords an apt illustration. This excellent charity wants money to enable it to enlarge its buildings to meet the great pressure on its resources. Professor McHardy said that £8,000 were really required and then he referred to the point I have mentioned above. He said as they did not get into debt they were awarded a very small sum from the King's Fund—in fact, not one fortieth of the grant given to the Royal Ophthalmic, but it is certain that the Royal does not do double as much work as the South London. He hoped the managers of the King's Fund when they became more acquainted with the facts in this case would act more liberally.

For my part I would say act more justly. The truth is the Distribution Committee of the Sunday Fund set its face tone of these agencies under an amount of prejudice against the smaller institutions which was quite inexcusable, and they went about to establish their own notions in a manner sure to bring about reaction.

The Temperance Hospital annual meeting was held last night, Sir Geo. Livesey presiding. The in-patients during the year were 1,376, out-patients 8,413, and casualty cases 14,524. Sir W. Collins, the senior surgeon, commented on the progress of the hospital from the point of view of the medical staff. Dr. D. Burns pleaded for more subscriptions, and the proposal to rebuild the out-patients department was approved.

The amalgamation of the two orthopedic hospitals is now practically complete. The Royal has sold its premises and vacates them on Lady Day, moving to the National which will be enlarged so as to accommodate 200 beds. It is also intended to have a branch in a northern suburb to contain 100 beds for cases which have made some progress but are not quite fit to be discharged.

The Irish Medical Graduates and Schools Association held their annual festival last night, Surgeon-General Sibthorpe, president, in the chair. There was a good muster of members and after the loyal toasts the Arnott medal was awarded to Mr. P. J. Freyer, who is a retired lieutenant-colonel of the Indian Medical Service and whose position as a surgeon is well known to you. Dr. MacNaug[illegible]

-Jones, who introduced him, said he held the record for largest fee ever received by a medical man, and when government wanted a part of that fee Mr. Freyer was, all Irishmen, "agin the government." He added that Freyer originated an operation the value of which is ognized all over the world and has increased the relief rded to human suffering and the prolongation of life. e medal was then presented by the president, and Mr. yer said that any merit of his work was due to his cation in Irish medical schools, and the development of t education in the Indian Medical Service.

A meeting of ladies was held at the Mansion House on nday at the invitation of the Lady Mayoress in support a proposed national training school for district mid-es.

Miss Gregory has propounded a scheme with the view ttracting educated women to this employment. Some er single ladies spoke in its support. It seems as if subject might be more appropriate to married women, t perhaps they have not so much time at their disposal. is proposed to build a hospital with seventy beds in ich the school should be carried on, where gentlewomen uld be trained in general and monthly nursing and rward in midwifery proper for six months. Hygiene, itation, physiology, etc., are to be taught, the whole rse occupying two years. The multiplication of pitals has already proved unsatisfactory, and the good ntions of the ladies might just as well be carried out in e that already exist. Either of our lying-in hospitals capable of doing all that Miss Gregory and her co-utors propose, and considering the many demands of se on the charitable it would be wiser to utilize them n to attempt to build another which is quite unneces-y.

Dr. Gordon of Exeter has communicated to the Medico-rurgical Society a somewhat curious observation which has made in certain cases of gastric cancer. He iced in several cases that the cardiac dulness was greatly ced and sometimes obliterated in the recumbent ture. He was so impressed with this that in five cases, finding it, he diagnosed cancer, and that was found to be Of course the normal dulness is not the same in the mbent as the erect posture and the observation ap-s to the recumbent only. The sign is not constant. ay precede cachexia, wasting and loss of skin elasticity. absent in the early stage it may develop slowly toward close. It is rarely found in other diseases—even in coma. Other causes of alteration in the area of cardiac lness must of course be rigidly excluded.

The explanation was suggested that the margins of the gs extended across the front of the heart, and this found so on post-mortem, owing to loss of elasticity, h as is often observed in the skin over an abdominal cer.

Sir D. Powell asked if any microscopical investigation had n made as to the condition of the lung tissue, as it med desirable for a long series of cases to be examined. e cancer hospitals might make observations. Dr. rdon replied that he had examined the lung tissue of e case with a microscope, but had not detected any nge. He thought the loss of elasticity was due to a ndition which could not be shown microscopically.

Mr. Betham Robinson then described a typical case of operitoneal hernia and exhibited the specimen which wed the anatomical features of these rare cases. The c is an extensive one and its approximation to the adder remarkably close, but the differences from pre-ical hernia are obvious. A small diverticulum to the ner side of the sac agrees with Rokitansky's description. Mr. McAdam Eccles remarked on the great preponder-nce of this form of hernia in vesicles. In fact, he believed only occurred in them, though the interstitial variety more common in females. Mr. Robinson, however, held at a crural form of properitoneal hernia does occur in males.

Two years ago Dr. Byron Bramwell showed a case of fantilism to the Edinburgh Medico-Chirurgical Society. he case was a boy of nineteen, who looked not more than leven. He was four feet four and one-eighth inches in eight and weighed four stones seven pounds. For some ine years he had stopped growing, had suffered from hronic diarrhœa, five or six motions daily, otherwise he as well formed and there was no sign of sporadic cretin-m. Dr. Bramwell attributed his state to defective ancreatic secretion. This appeared from (1) excess of at in the fæces which diminished under pancreatic ex-tract; (2) urine on a milk diet contained a small amount of phosphoric acid which increased much under the ex-tract; (3) capsules containing iodoform in a covering in-soluble in gastric juice but soluble in the pancreatic secre-tion were given; on testing the saliva an hour afterward there was no evidence of iodine or iodates; but when the capsules were given along with pancreatic extract the reaction was readily perceived. Dr. Bramwell has now brought the boy before the society again to show that under treatment by pancreatic extract he has grown five inches in height and increased in weight to eight stones eight pounds, looks much older and his sexual organs have developed. Not having found records of similar cases, Dr. Bramwell pronounces this a new disease, happily curable by supplying the deficient secretion. Dr. J. Thomson showed two similar cases of infantilism—both males, eighteen and twenty-four, but with the general appearance and size of boys of seven or eight and ten respectively. Both have suffered for years more or less from dyspepsia, abdominal distension and diarrhœa, and it may be that in these also the pancreas is at fault. In one of these cases the diarrhœa is not constant but recurs some six or seven times a year. They have not been long under observation, but will, no doubt, be put on pancreatic extract and careful notes made of their cases.

Foreign bodies in the air passages often call for resourcefulness in dealing with them, as well as for diagnostic acumen in being sure of their position, or even of their presence. A case was communicated to the Clinical Society last week in which a boy of five was admitted to hospital four days after swallowing a glass stopper. There was a temperature of 102.8 and wheezing on deep inspiration. Consultation indicated obstruction in the left bronchus, and *x*-rays showed an indefinite shadow there. On tracheotomy the foreign body could be felt by a probe passed down. On failure to extract it with forceps, a loop of wire was passed with success and the wound closed after cleansing from some pus. Four days later the wound was nearly healed and the physical signs normal.

Dr. Taylor mentioned a case supposed to be phthisis, for which the patient was sent on a sea voyage, but one day he expectorated a little blood and a bit of a broken tooth, after which he soon regained health. Dr. Eastes thought inversion valuable when the body is loose. Mr. Makins mentioned a case of suspected foreign body which proved fatal and was found to be due to a caseating bronchial gland. Mr. Hutchinson, Jr., thought the stopper was probably virulently septic, hence the pus. He found silver wire the best means of extraction.

The antivaccinationists have been holding high revel in a two days' conference when their leaders denounced the "conscience-clause" and demanded "perfect freedom" to go unvaccinated. The action of some of the magistrates was described by one speaker as "insensate folly and insolence" and declared that the Government disregarded cases to which their attention was called in Parliament or otherwise. The managers of the Children's Country Holiday Fund were called to account for requiring the children they benefited to show they had been vaccinated, and it was proposed to raise another fund to take the excluded children for a holiday. Mr. Grant, M.P., counseled a policy of resistance, "holding the fort," but making no attempt to press forward at the present time.

A two days' trial for libel brought by the antivaccination surgeon, Mr. Hadwen, has ended in a verdict for one farthing damages against Mr. Price, surgeon, who had written to the Local Government Board that a child's death certified by the plaintiff as due to some other disease had been caused by smallpox. The defence was that the communication was privileged.

Sir Lander Brunton has resigned the physiciancy to St. Bartholomew's Hospital and has been appointed consulting physician.

Sir Samuel Wilks has continued very ill during the week but yesterday's bulletin is rather more cheerful. It reads: "Sir Samuel has had a better night, and is taking nourishment with some pleasure."

The Edinburgh Obstetrical Society has adjourned for a month as a mark of respect for the late Dr. Milne Murray, whose death I mentioned to you February 19.

The deaths are announced of Mr. George Welford, consulting surgeon to the Sunderland Infirmary, aged eighty-nine, on the 11th inst.

Mr. George Archer, a nonagenarian, born in 1811, a veteran Poor-Law Medical Officer who was awarded a pension.

Dr. Augustus Brown, formerly demonstrator at St. George's Hospital and a London practitioner, who later retired into Kent on account of failing health. He died on February 17, aged seventy-five.

Mr. John S. Bartrum of Bath, aged eighty-seven. He was surgeon to the Mineral Water Hospital and Eastern Dispensary for many years. He had twice been Mayor of Bath, his native city, and took great interest in public matters. He was a J. P.

Dr. John R. B. Dove, on January 27, aged sixty-seven. He was a distinguished alumnus of the London Hospital, where he carried off many honors, as he did also at the University of London, where he took his M.B. and B.S. in 1867 with honors in medicine, surgery, and midwifery. He settled at Pinner, and was surgeon to the West Hunts

Infirmary, which his fellow students and teachers thought scarcely gave him scope for his remarkable abilities. He retired two years ago from ill health and was the recipient of a handsome testimonial.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

SYPHILIS DYING OUT—ETIOLOGY OF TABES—INFANTILE TUBERCULOSIS—MILK NO CAUSE OF TUBERCULOSIS—EXPEDITION FOR YELLOW FEVER—DR. MUGDAN AND THE REICHSTAG—OBITUARY.

BERLIN, March 1, 1904.

SYPHILIS, which for centuries has been a disease of the severest kind, seems to be on the decline. Dr. Iwan Bloch made this statement at a meeting of the Society for Prevention of Venereal Diseases. We know that since syphilis was brought from Haiti by the sailors of Columbus to Europe, according to the bishop, Las Casas, it has lost its great virulence. The symptoms do not appear as severe as they did some hundred years ago. The very fact that for generations syphilis has been prevailing, has rendered the people immune against the disease.

In France, where the disease was at the time of Louis XIV an every-day disease, it is now less frequent. Besides our knowledge of the treatment of syphilis has increased, and mercury combined with iodides has no doubt a specific effect. The difficulty lies in attributing many symptoms to the syphilitic infection. The words of Professor Fournier, the well-known syphilologist in Paris, must be remembered: "On m'a reproché d'avoir vu partout la syphilis; jeregrette de ne l'avoir pas vu assez souvent."

Indeed, is syphilis the cause of so many diseases of the nervous system? The old dispute whether tabes dorsalis is caused by syphilis has recently been again discussed by Professor Erb of Heidelberg. According to his statistics he has proved a syphilitic infection of eleven hundred patients with tabes. Erb goes even so far to pretend that hereditary syphilis may cause tabes.

At a recent meeting of the Berlin Medical Society, Dr. Westenhöffer read a paper on the origin of tuberculous infection. He had studied this question under the late Professor Virchow and has continued his researches with Professor Orth. His experiments made on guinea-pigs, rabbits, and cows led him to believe that an inflammation of the vaccinated spot takes place, then the glands become inflamed, and of the organs the spleen and liver become infected, very rarely the lungs. The infection goes through the lymphatic system, but the nearest situated glands do not become inflamed first. Westenhöffer concludes from this fact that there must be in the human organism some communications between the lymphatic vessels, so that the infection is carried to some distant spot, a fact which seems to be proved in the case of carcinomatous infection when not always the nearest glands become infected.

Considering infantile tuberculosis, he noted the fact that infants never become infected until they are three months old. Dentition begins in the third month, and the mucous membranes of the gums are affected. It is known to what an extent children take playthings into the mouth, and it is to be supposed that the bacillus tuberculosis comes with these playthings into the child's mouth and then penetrates through the affected mucous membranes of the gums. Either an inflammation of the cervical glands results, which is operated upon and extirpated, or bronchial tuberculosis occurs which may lead to phthisis, or to miliary tuberculosis. Many children, however, do not show any signs of tuberculosis for some years, and only at a later age when life's pressure comes upon the person, the tuberculous process, phthisis pulmonis, results. Westenhöffer believes that meat cannot cause tuberculous infection. Professor Orth, discussing Westenhöffer's communication, said tuberculosis of the intestines of infants' was rarely noticed. Of 1522 dissections made at the Berlin Pathological Institute, only 3.4 per cent. showed signs of a tuberculous process of the intestines. He also thought tuberculous infection at a later age was caused through inhalation, contrary to Behring's opinion, who holds that the seeds of tuberculosis take root laid in the first year.

Dr. Arthur Meyer called attention to the fact that milk is given in England not boiled, and though we have been told that milk contains many tubercle bacilli, yet the the mortality of tuberculosis is not as large in England as it is in Germany. He believed that Behring was wrong in denying an infection through inhalation. The formalin-milk recommended by Behring caused an inflammation of the palate. Dr. Ruhemann thought that influenza was a predisposing cause of the tuberculous process. Experience shows that a tuberculous person gets rapidly worse when the bacillus of influenza affects him. He wished to see the phthisical patients wear, as in former days, a mask against a renewed infection of any kind.

An expedition to study yellow fever is to be sent to South America at the expense of several Hamburg business men. Dr. Otto and Dr. Neumann of the Berlin Hygienic Institute have been appointed as medical superintendents.

Dr. Mugdan, who became a member of the Reichstag at the last elections, has demanded in the Reichstag that club patients should be allowed to consult the doctors they choose, and that they should not be compelled to consult the club doctor alone. Dr. Mugdan's proposal met with the approval of the Reichstag in general, and Count Posadowsky, minister for home affairs, granted this demand. The Minister has informed the Reichstag that the Government had thought it necessary to create a new professorship at the University of Berlin, devoted to diseases of the working classes and of some special trades.

Prof. Adolf Gusserow, professor of obstetrics and gynecology at the University of Berlin, will soon retire from his post. His successor is to be Dr. Bumm, professor at the University of Halle. Dr. Gusserow has been for many years an active member of the medical profession in Berlin, and his clinic paid special attention to the instruction of students and nurses in midwifery.

Dr. Jurasz, professor of diseases of the nose and throat at the University of Heidelberg, has been appointed "professor ordinarius" at the University of Lemberg. Of all German universities only Rostock enjoys professores ordinarii, *i.e.* professors with a fixed income given by the university. The foundation of this professorship for nose and throat diseases is due to the Grand Duke of Mecklenburg-Schwerin.

Dr. Ziehen, professor at the University of Halle has been appointed professor of psychiatry to succeed the late Professor Jolly.

Dr. Emil Ahting, assistant at the Hamburg Eppendorf Hospital, died of septicæmia following infection during an operation.

Progress of Medical Science.

The Boston Medical and Surgical Journal, March 17, 1904.

Forcible Correction in Lateral Curvature of the Spine.—Robert W. Lovett declares that the problem to be met in the treatment of severe lateral curvature with fixed bony changes is a perfectly definite one. To expect free muscular exercise to straighten, to any extent, curves caused by deformity of the vertebral bodies seems unreasonable. Gymnastic treatment after forcible correction and in connection with effective support is, however, of the greatest value, and is one of the essentials of successful treatment. As to intermittent force and gymnastics, the correction or other part of the treatment is to be obtained by general and special muscular exercises, including the raising of heavy weights, etc. The best development of such corrective work is to be found in the form of apparatus devised by Schulthess. The corrective effect of braces in straightening the curves in severe scoliosis is a very slight one. Braces and corsets are, however, of the greatest use in maintaining the correction obtained by the use of force or by other means. Prolonged recumbency in the treatment of scoliosis is the relic of a bygone tradition and need not be discussed. The question of the operative relief of scoliosis is still *sub judice*. The writer believes that the best chance of improvement in cases of severe scoliosis is to use severe force to secure an improved, and if possible an over-corrected position temporarily; to retain as much as possible of the position thus secured during some part of the growing period. The writer believes that even in adults, much correction may be accomplished by the use of properly directed side force. He describes two excellent retention jackets. With regard to the relative merits of the suspended and the prone position, suspension works on the whole spine, and distributes itself and untwists the rotation while it straightens the lateral curve, but it is not corrective enough by itself. In the prone position fainting is less likely; there is less discomfort, and far less force is required to obtain a definite amount of correction, because the force is more economically applied, and the back can be inspected through the early part of the process. The writer thinks it a great advantage to have the lumbar curve held by the jacket as flat as possible, as he believes that a corrective extending force is thus exerted upon the dorsal curve. In presenting the claims of efficiency of the apparatus, he says that the most economical use possible is made of the corrective force by applying it sideways, and thus less force is required, or the same amount of force will do more than in extension of the spine. The force is applied to the spine while slack, and not made tense by extension. Side correction is made by one part of the appliance. Correction of rotation is made by another part of the appliance. The pelvis is held in a position which ensures some flattening of the lumbar curve

ich in the upright position tends, on account of the bal-ce of the patient, to bring about straightening of the rsal curve. General pathological considerations would m to indicate that retention in the corrected position uld induce changes in the shape and relations of the sshapen bones.

urnal of the American Medical Association, April 2, 1904.

A Study of Gonococcus Metastasis; with Report of a se.—J. M. Cooper reviews the literature of the subject d reports the case of a married woman of forty years, ose husband had been under treatment for gonorrhœa. e month later she complained of sharp, shooting pains und the base of the right thumb and index finger—lead-g up to a swelling of the whole hand. In about a week incision was made over the proximal phalanx of the lex finger and a little pus evacuated. Immediate lief followed, but two weeks later it became necessary make free incisions into the palm and dorsum of the nd. Considerable pus was evacuated. The pus sacs re curetted and washed out thoroughly with a hot car-lic solution. The subsequent treatment consisted of hot chlorid irrigations and antiseptic dressings. Recovery s uninterrupted, but the involvement of the flexor don resulted in its shortening, which prevents the com-te extension of the index finger. There was no anky-is of any of the neighboring joints. This fact, together th the evident involvement of the flexor tendon, indi-es that the condition was purely a tendovaginitis. cteriological examination of the pus gave the reactions gonococci.

Treatment of Typhoid Perforations.—This subject is cussed by L. Frank, who reports a personal case result-g fatally. His general conclusions are as follows: (1) nforations are to be expected in about 2.5 per cent. of all es of typhoid fever. (2) Prompt surgical intervention the best and only logical treatment. (3) Early diag-sis is most desirable, and will be the means of greatly ducing the mortality, as 55 to 60 per cent. would recover.) Diagnosis, sufficiently early to achieve these results, n only be made by careful watching, treating all cases serious ones, and properly interpreting the early, even e preperforative, symptoms. At the first indication of s stage the surgeon should be in consultation and pre-ed to operate. (5) The sphygmomanometer should me into general use as an important aid to diagnosis.) More cases die from delay than from errors in surgical chnic. Therefore, in doubtful cases, though a mistake y be made and no perforation found, we should operate.) No case, unless dying, is so desperate as to be beyond me hope of saving. So, in operating, we must lose no me, and be sure to drain. (8) We should get into and t of the abdomen as quickly as possible.

Stricture of the Female Urethra.—H. L. E. Johnson gives general description of this condition and reports six sonal cases due respectively to gonorrhœa (one), gun-t wound (one), and unknown causes (four). In one e there were five strictures. He lays down the follow-general rules for treatment: Acquired stenosis or resia calls for gradual or rapid dilatation with olive-nted sounds, bougies, metal catheters, urethral or erine dilators, and, in some cases, cutting or incision. nstitutional medication should invariably follow sur-al correction of stenosis or atresia from urethral chancre. catricial bands in the vagina contracting the urethra ould be incised, stretched and loosened up. Bladder nd urethral irrigation and flushing should be practised all cases. Treatment of congenital atresia will depend on the extent and the character of complications. It may be necessary, in extreme distention, to puncture the blad-der to evacuate its contents, or incise, making either a vesicovaginal or a urethrovaginal fistula, before opening the atresia, closing the incision or fistula after the integrity of the reconstructed urethra is assured. Atresia com-plicated with vesicovaginal fistula should be dilated or incised, subsequently closing the fistula. Atresia com-plicated with urine escape at umbilicus through patulous urachus, should be dilated or incised without making a vesical fistula. After changing the course of the urine the patulous urachus is supposed to close and atrophy.

The Medical News, April 2, 1904.

Abdominal Ascites with 150 Tappings.—E. K. Browd reports the history of a patient under his care. During the ten years of her ailment the patient has been tapped 150 times. The first 3 tappings gave 45 quarts, and next 147 tappings at 9½ quarts, 1,396½ quarts; or, together, 1,441½ quarts, or 2,883 pints, or fluid pounds; or, 360⅜ gallons. The patient is sixty-nine years old, and is in tolerably good health, unimpaired by the long, continuous drain of the constitution and obstructive circulation to the vital organs. The patient has always refused surgical interference, in spite of the possibility of a permanent cure of the chronic abdominal ascites by a radical operation which would tend to break up the old adhesions and fasten the omentum to the parietal peritoneum, thus relieving the obstructive portal circulation, and establishing a peritoneal circulation.

The Importance of Dropsy as a Symptom.—A. C. Morgan states that, as a general rule, the significance of this symptom can be interpreted as follows: (1) Initial dropsy of Bright's appears as œdema, and under the lower eyelids, seen upon arising in the morning, but disappearing by night; (2) in valvular heart disease, myocarditis, lung or blood conditions its first appearance is in the ankles, appearing late in the day and increasing toward night, and (3) hydroperitoneum or ascites is the first dropsy due to failure of compensation in the portal circulation, as in cirrhosis of the liver. The local œdema resulting from a small abcess is slight in importance, but becomes increased in value in œdema of the chest wall as indicating empyema. The early œdema of valvular heart disease such seen in the ankles, indicates the gradual weakening of the right ventricle, due to fatty degeneration of the muscle. This may be present for years and not advance much, until some sudden strain or intercurrent disease such as bronchitis or grip overcomes all the reserve force, and the patient dies from sudden pulmonary œdema. General dropsy or anasarca, due to Bright's or heart disease, may be recovered from if the patient be in the prime of life, possessed of good muscle tissue, and if the poison or factor that has caused the condition be entirely removed. A patient who has once been the subject of general dropsy, regardless of the cause, is in imminent danger of a recurrence, and a fatal termination. When dropsy ensues during the course of any cachectic conditions, as tuberculosis or cancer, it can be inferred that the patient is nearing the last stage of the disease. Unless he respond to treatment, the end is not far off. Dropsy is an important symptom, and the cause must always be sought for and removed.

New York Medical Journal, April 2, 1904.

A Case of Infection with the Bacillus Aerogenes Capsulatus.—The first patient of S. W. Sappington was a widower of thirty-nine years, brought to the hospital with the history of sudden illness and a fall on the street. A diagnosis of acute alcoholism was made. Later vomiting of coffee-ground material, and of dark clotted blood came on. Eighteen hours afterward he died in a cyanotic condition. Autopsy revealed an emphysema of the subcutaneous tissues. The liver was the seat of an atrophic cirrhosis. Bacteriological examinations of the spleen and heart were made. The superficial portions of the latter showed ordinary staphylococci while the deeper portions showed the bacillus aerogenes capsulatus. The second patient was a man of sixty-five years, who died some fourteen hours after coming under observation, having presented marked œdema of the legs, effusion in both pleural cavities and a rapidly failing heart. Autopsy showed the presence of local interstitial emphysema, and of a remarkable amount of gas in a blood-vessel, and it was possible to demonstrate from the blood a bacillus corresponding precisely in points of form and staining reactions with Welch's bacillus, a condition forming with the conspicuous absence of gas cysts in the organs an atypical group of phenomena. It was not possible to demonstrate the channel of the entrance of the infection.

Some Drug and Alcoholic Habitues.—S. B. Lyon reports a series of cases. One was that of a woman of good position addicted to drinking sherry, who chose to live in shabby quarters and associate with people much beneath her. Her mind became dull, she quarreled with her neighbors, was finally adjudged insane and committed. Withdrawal of the liquor and the institution of a tonic regimen restored her after a few months to a normal state. A second case was that of a woman of high social standing who, from alcoholic excess, became acutely maniacal, noisy, destructive and controlled by hallucinations. Six months were required for a cure. Similar cases are narrated in men. Lyon thinks that in the treatment of such cases from the higher walks of life, the moral treatment is, as concerns permanent results, more important than the medicinal. His therapeutic treatment of drug cases has for several years involved the sudden withdrawal of the drug and the substitution of a sustaining agent, such as strychnine and capsicum, etc., upon the theory that a more thorough elimination of the opium from the system is obtained by the copious discharges which occur. The alcohol may be more gradually withdrawn, but a very quick return to the natural conditions is his usual practice. He has found the systematic bathing that he uses relieves the discomfort, itching, etc., which sometimes follow drug withdrawal, and produces a good mental impression.

American Medicine, April 2, 1904.

Toxæmia Associated with Tuberculosis of the Cervical Lymphatic Glands, with Report of a Case.—Arthur W. Elting reports the case of a man aged twenty-six. The right side of the neck presented an extensive tumor mass. On admission to the hospital his condition seemed most critical. He showed marked symptoms of toxæmia. Under ether anæsthesia the enlarged glands were carefully excised. They presented the typical macroscopic picture of tuberculosis. Tubercle bacilli were demonstrated. Ten days after his entrance to the hospital he was discharged in excellent general condition. The writer has not been able to find in the literature reference to a similar case in which so profound a toxæmia has developed in association with a localized focus of tuberculosis of the lymphatic glands, and in which so rapid a recovery followed the removal of the focus.

Sarcoma of the Nasal Passages: An Inductive Study Based on the Records of 150 Cases.—J. A. Watson reports that since the middle of the last century about 200 cases of sarcoma of the nasal passages have been put on record. Any of the different varieties of sarcoma may be found in this region. Round-celled sarcoma, and especially small round-celled sarcoma, is most frequent. It is questionable whether the comparative frequency of melanosarcoma (about 7 per cent.) is paralleled in any part of the body except the skin and choroid. Sarcomas of the nasal passages are usually soft, succulent, and vascular. The particular point of origin of nasal sarcomas is of great interest. The middle turbinate and ethmoid region seem to be the most common site, though closely followed by the septum. The average life of the patients is a little less than thirty-nine years. The male sex is far more often affected than the female. Nasal stenosis is the most constant symptom. Spontaneous hemorrhages constitute the next most common symptom. It is probably true that sarcoma of this region manifests a less malignant tendency than when occurring elsewhere. The occurrence of metastasis is an extremely rare event. Apart from surgical measures, the only treatment worthy of consideration is that by toxins. The writer has not observed any noticeable improvement in this series of cases from this treatment. Out of forty-eight cases the percentage of cures obtained by radical external operation was 39.58. In sixty-four cases in which intranasal operation was performed, the percentage of recoveries was 54.68. These results surely justify the adoption of the milder measures in selected instances, at least. Dawbarn's procedure of exsecting the external carotid artery appears to be an improvement on simple ligation, and gives promise of at least rendering operable many otherwise inoperable growths.

The Lancet, March 26, 1904.

Acute Yellow Atrophy of the Liver.—The patient of J. Edwards and M. H. Smith was a man whose first symptom was jaundice, increasing in spite of all remedies. In about a week he became delirious and uncontrollable, with diminution in the area of liver dulness, while that of the spleen was somewhat increased. The heart and lungs presented nothing abnormal. Considerable bile pigment appeared in the urine, which was passed in bed. The bowels were obstinately constipated. In the course of two days coma developed, in which he died. No fever was present at any time. A diagnosis had been made of acute yellow atrophy of the liver, and its correctness was confirmed by autopsy.

Hysterectomy for Uterine Cancer with Co-existent Pregnancy.—I. Macdonald and W. A. Mackay report the case of a primipara, aged thirty-six years, who for six years had suffered from lumbar pain, menstrual disturbances, and leucorrhœa. In addition, she had had several recent gushes of an offensive fluid. The condition was diagnosticated as cervical cancer and pregnancy. The abdomen was opened below the umbilicus, the uterus lifted forward, while the upper borders of the broad ligaments which lay perpendicularly were divided between two ligatures outside each ovary, and the round ligaments were similarly treated. The patient was now placed in the Trendelenburg position, which, added to the weight of the uterus, pulled the cervical portion well out of the pelvis. By means of a sound the relations of the bladder, which lay lower than would have been supposed were determined. Peeling the bladder downward, the uterine arteries were ligatured on both sides and the anterior vaginal fornix was opened on a curved sound. The section of the vagina was carried rapidly round, the wall on the left side being cut well beyond the disease. The operation was concluded in the usual manner. In six weeks the patient was walking about, and was remaining well six months later.

On Treatment with Antituberculous Serum.—A. Mar morek gives the results received by the use of the serum prepared according to his general methods. In gener they are distinctly favorable. He finds that some pa tients manifested an intolerance to the injections, an this he ascribed to the formation of antibodies of a albuminoid substance, for when he changed the tec niques, he noticed that the reactive effects of the serum- such as fever, infiltration, and œdema at the point injections, and even swellings of the glands—became mo and more rare, and even when they did appear, were wea unimportant, and transient. The tolerance of the serum is to-day, according to his method of application, abs lute, and as the injections continue, they seem to agr more and more with the patient. This point of toleran is reached by a graded series of injections with intervals rest. As a general statement, the doses should be adapt to the individual constitution and the state of the disea of the patient. A series of daily doses during from fo to five days agrees well with the patient, especially if t tween each two series there is an interval of three or fo days. After two or three series of injections, it is well discontinue them for a week or a fortnight. The do for rather chronic cases is ordinarily five cubic centimete while in acute cases as much as from twenty to thir cubic centimeters can be used daily during the we Even children support this dose without danger. T day the reactions take the form generally of the w known erythemata, which quickly disappear.

Pathology and Surgery of Certain Diseases of the Pa creas.—A. W. Mayo-Robson concludes the third Hu terian lecture, with some statistics as to the after-resu of operation in certain cases of pancreatic disease. one case, in which the cause was due to pancreatic calc these were removed both from Wirsung's and Santorin ducts, with complete recovery, and the patient now well. In 27 cases of catarrhal or interstit pancreatitis, in which gallstones were found obstruct the pancreatic portion of the common duct, choledoch omy in 19, cholecystotomy in 5, and cholecystenter tomy in 3, were followed not only by immediate recove but, as ascertained by recent reports, the patients now well, except one who has since died from acute br chitis, one who is suffering from cirrhosis of the liver, a one who, eight and a half years subsequently to operati is apparently well, though sugar has recently been fou in the urine. In 24 cases, in which obstruction to the co mon bile-duct was due to an inflammatory condition the pancreas compressing the bile-duct, though probab in many of the cases originally due to gallstones, in which gallstones were not actually present at the ti of operation, the bile-ducts, and thus indirectly the pa creatic ducts, were drained, in 12 cases by simple cho cystotomy, and in 9 by cholecystenterostomy; in 3 ca adhesions were separated, and no drainage of bile-du was performed. Of these 24 cases 22 recovered. T out of 51 patients died as a direct result of the operati one a cholecystotomy undertaken in a patient reduced the last stage of exhaustion before a surgical opinion w sought, and in which at the necropsy a cirrhotic condit of the head of the pancreas was found, and a second which a cholecystenterostomy was undertaken in presence of adhesions that appeared too formidable deal with, considering the poor condition of the patie who succumbed a few hours later. In this case necro revealed a stone in the pancreatic portion of the comm duct, which should have been discovered had the patien condition permitted a thorough exploration. Eight completely recovered. Of three patients in whom the pa creas was found enlarged at operation, nothing beyo separation of adhesions and manipulation being done, recovered.

Deutsche medizinische Wochenschrift, March 17, 1904.

Is There a Differential Diagnostic Method for Human and Animal Blood by Means of the Precipitins?—A. Wasserman asserts his claims to be considered the originator of the precipitin method for the differentiation of albumins from different species of animals, and states that the term "differential blood test" applied to the method or modifications of it by Uhlenhut and other authors is a misnomer. What the method does is simply to provide an accurate means of determining whether a certain albumin is of human or animal origin, but further than this it cannot go, for spermatic fluid, milk, saliva, pus, etc., all give the same reactions as blood. The application of the method to forensic uses makes misconceptions as to its nature of importance, and to avoid confusion the term "blood differentiation method" should be discontinued, and the correct one, "albumin differentiation method," adopted. No biological method for the differentiation of human and animal blood exists, and the precipitin method, which was

scovered by Tchistovitch and Bordet, was first elaborated d applied to the practical differentiation of human and imal albumins by A. Wasserman.

Blood-pressure Determinations in Arteriosclerosis.—Sada made records of the arterial tension in two hunred and six cases of arteriosclerosis, using for the purpose e sphygmomanometer of Riva-Rocci as modified by v. ecklinghausen. The improvement consists in the arm ece, which is made 14 cm. in breadth and is surrounded y an unyielding metal collar. The author regards the rmal pressure range as varying between 90 and 100 mm. Hg., and considers as abnormally high pressures above o mm. of Hg. Between 120 and 130 mm. of Hg. lies indeterminate range of 10 mm. which cannot be held sitively abnormal. Of the patients examined only 12.3 r cent. showed a definite rise in pressure, which usually aried between 130 and 160 mm. of Hg. In two-thirds of ese cases the aortic second sound was accentuated, and in ese the pressure exceeded 140 mm. of Hg. An accenated aortic second sound was found in a larger proporon of cases than this without the coexistence of any monstrable rise in pressure in the brachial artery. The ddition of interstitial nephritis to the arteriosclerosis used higher blood-pressures than the latter alone, the essure always exceeding 150 mm. In general it may be id that pressures above 160 to 170 mm. of Hg. always ve reason to suspect the presence of an interstitial phritis, even if, as is often the case, the urine contains albumin at the time of examination.

Berliner klinische Wochenschrift, March 14, 1904.

Tabes, Aneurysm of the Aorta, and Syphilis.—Ruge has ne over the statistics of the Friedrichshain Hospital ith the intention of checking the figures of Lesser, who und that evidence of syphilis was present in 28 per cent. ninety-six cases of tabes autopsied in the Moabit and rban Hospitals and that the percentage for aortic neurysm was about the same. In his ninety-six cases of bes, aneurysm occurred eighteen times; that is, about one betic in five had an aneurysm. The author's figures ken from the records of 11,000 autopsies done in the last ne years give a much lower proportion of aneurysms to bes. Out of sixty-four cases of tabes only three had also d aneurysms, that is, only one in twenty-one. Of the xty-four cases eighteen gave positive evidence of syphilis the post-mortem table, but this figure does not inude suspicious cases or those in which the patient had mitted infection; but the cadaver exhibited no signs of e disease. The author's figure of 28.5 per cent. of yphilitics out of sixty-four tabetics corresponds closely the percentage of Lesser based on ninety-six cases. ne hundred and thirty-two cases of aneurysm were und, but only 12.8 per cent. of these showed post-mortem aces of syphilis.

V. Behring's Theory of Tuberculous Infection.—Spengler scusses the theory v. Behring has recently promulgated regard to the mode of infection of tuberculosis and mes to the conclusion that the latter's views are untenble. He does not accept the fundamental assumption v. Behring that human tubercle bacilli and those of erlsucht are identical, and points out that marked ultural and morphological differences exist between the o. For example, the bacilli of perlsucht thrive better hen air is excluded from the culture medium, whereas a rtain degree of ventilation is essential for the tubercle cillus. The discovery of the permeability of the intesnal mucosa was adapted to lead to premature conclusions and the post-mortem findings do not bear out the eory of universal primary intestinal infection. The thor's observations have invariably been to the effect at the bronchial glands are the site of the first infection and that the intestine and mesenteric glands are free from cilli and tuberculous foci. In order for the tubercle cillus to remain in the body in an inactive condition for fteen to thirty years as v. Behring assumes it does, bercle formation is absolutely essential. The tubercle cillus when immersed constantly in fluid, as it would be if free in the body, dies in a short time even in the best trient medium and the formation of the nonvascular bercle is its means of escaping this adverse environment in the body.

What Are the Least Demands to Be Made of a Milk for Infant Feeding?—Engel says that in Germany the only milk consumed by the lower classes that approaches the hygienic standard is that produced by the large dairy concerns. The special "children's milk" must conform to such stringent regulations that its production becomes very expensive, while the regulations for ordinary milk are far too lax. The percentage of fat required is only 2.7 per cent., which permits extensive adulteration with skimmed milk or water, and very little stress is laid on the health of the cows, the cleanliness of their surroundings or the bacterial content of the milk. The lowest requirements which, according to the author, should be made are that the cows shall be healthy, that the milk shall be obtained in a cleanly way, and that it shall be cooled immediately after milking. By enforcing these regulations satisfactory milk can be produced without greatly increasing the cost. Pasteurizing or sterilizing the milk, while the only way of making an impure product safe, is undesirable, as it not only alters the digestive properties of the milk, but is insufficient since it does not destroy the products of bacterial growth; and furthermore it kills the lactic acid bacilli, which are a useful protection against the overgrowth of other organisms. The author also suggests the following formula for humanized milk. One-half liter of clean milk, the same amount of water, 15 gm. of butter (or about a level tablespoonful), and 36 gm. (or about two tablespoonfuls) of milk sugar are boiled together and cooled to a tepid heat. Then one-half an egg is added, under constant beating. This mixture is cheap, is very digestible, and has almost the same composition as human milk.

Münchener medizinische Wochenschrift, March 15, 1904.

The Agglutination of Typhoid Bacilli by the Serum of Jaundice Patients.—Steinberg tested the agglutinating power of typhoid bacilli in twenty-two patients suffering from jaundice due to various causes. In fifteen the reaction was positive only in dilutions of 1–20 or 1–40. These comprised six cases of catarrhal jaundice, two of gallstones, three of carcinoma of the biliary passages, one tumor of the gall-bladder, one of acute yellow atrophy, one of general sepsis, and one of febrile jaundice. In the seven other cases agglutination was produced at dilutions greater than 1–40, the two highest being in patients who had previously had typhoid fever. The other five cases included two of catarrhal nature, and one each of carcinoma of the liver, febrile icterus and icterus of doubtful etiology. The author explains the occurrence of the agglutination by assuming that it is due, not to the jaundice, but to some infection (proteus, coli communis) accompanying or causing the icteric condition.

The Occurrence of Typhoid Bacilli in the Urine and Fæces of Typhoid Convalescents.—Herbert had an unusually favorable opportunity for studying the persistence of the bacilli in typhoid convalescents during an epidemic of the disease in the Insane Asylum at Göttingen. The urine and fæces of ninety-eight patients were examined, first eight days after defervescence, and a second time eight days later. If both examinations were negative the patient was considered free from bacilli, but if the result at either time was positive, the examinations were repeated at intervals of eight days until they proved negative on two successive occasions. The method employed in making these very numerous cultures was that of Drigalski and Conradi, which was found very satisfactory. "Two hundred and twenty-eight examinations of urine were made and two hundred and sixteen of fæces. Out of the ninety-eight cases, bacilli were found in the urine in 18 per cent. of the number, and in the fæces in only 3 per cent. It was observed that the bacilli persisted longest in the excretions of those patients who had suffered the most severe course of the disease, or had had relapses. In only one case could the bacilli be demonstrated after the first four weeks of convalescence, the time before disappearance ranging between eight and twenty-seven days after defervescence, and averaging fifteen days. The most important feature of the investigation is the fact that it is principally the urine which harbors the bacilli and forms a source for their dissemination.

The Origin of Tuberculosis with Special Reference to v. Behring's Theory.—Cornet takes a stand against the recent teaching of v. Behring to the effect that inhalation tuberculosis is too infrequent to be considered, and that it is primarily the infants who are infected, and these principally through milk. Adults who develop the disease do so as a sequence of infantile infection which has been latent since that time. Cornet takes up the various dicta of v. Behring in detail and refutes them wholly. The mortality statistics of Prussia show that the maximum mortality from tuberculosis is late in life and not during infancy, as should follow the widespread infantile infection v. Behring postulates. The author's experiments on several thousand animals show that tuberculous infection always leaves its mark either directly at the site of entry, or else in the nearest lymphatic glands. From here the infection proceeds only gradually along definite lines which can always be demonstrated after death unless general dissemination of the bacilli has taken place. This is not in accord with v. Behring's idea that the bacilli, having obtained entrance to the body by piercing the alimentary mucosa, are free to select any gland in the body in which to settle without leaving any

trace of their progress. The author's experiments have demonstrated the existence of inhalation infection, and a further ground for disbelieving v. Behring's views lies in the enormous preponderance of tuberculosis among workers at certain trades (stone-cutters, metal-grinders, etc.) who must have been in infancy exposed to the same chance of tuberculous infection as all others. Another fact of telling force in judging the question lies in the great diminution in morbidity from the disease which has followed the prophylactic efforts to prevent infection through safe disposal of tuberculous sputum.

French and Italian Journals.

Acetonæmic Vomiting in Pregnancy.—Lamacq, after reviewing the symptoms of acetonæmic vomiting in children, reports the history of a patient under his care. The patient, when about six months pregnant, after becoming extremely fatigued, was attacked by severe vomiting. This attack passed through several stages, till finally the vomitus became glairy, of a yellow color and flecked with blood. The color deepened to that of bile; the liver was large and painful. The breath had a pronounced odor of acetone. Acetone was found in the urine. Lamacq believes that the acetonæmic vomiting of pregnancy comes, as in the case of children, from hepatic insufficiency, at least in the cases in which there is a rapid absorption of albuminoids.—*Journal de Médecine de Bordeaux*, March 13, 1904.

Observation of a Patient Who for Ten Months Harbored a Foreign Body in the Bronchi; Recovery.—Georges Alexandre reports this unusual case. The patient was supposed at first to be suffering with acute bronchitis. The various ordinary remedies were administered, but to no avail. The patient became extremely emaciated. Insomnia and extreme fatigue were prominent symptoms. There was a little fever. The sputum was examined several times for tubercle bacilli, but these were never found. Ten months after the cough began, the patient ejected a bit of beef bone. She gave an account of the swallowing of the bone, being almost strangulated at the time that it happened. The symptoms grew gradually less, and after a year and a half, the cough ceased. The abscess which had been caused by the bone, and from which pus had freely flowed, healed. The fever disappeared, and the patient was restored to health.—*Journal de Médicine de Paris*, March 13, 1904.

A Conical Apparatus for Limiting the Action of the X-rays.—Carlo Luraschi has arranged a new apparatus for limiting the action of the *x*-rays to the diseased area which it is desired to treat. He endeavored to attain the maximum adaptability, lightness, ease of application to the desired part, ease of transportation, etc. He used thin plates of lead over tin for the sake of lightness combined with strength, and made his instrument in the form of a cone in order to intercept the maximum number of rays, and added a narrow flange at the base of the cone. The apparatus is provided with rings at its base and higher up, to which cords may be attached in order to suspend it in any desired position. He offers this shield to the public, as by its form, lightness, ease of adaptation to all regions of the body, and special constitution, the best device of the kind for limiting the anticathodal cone of the *x*-rays. It is most easy of application, of transportation, and as light and small as such an instrument can be made.—*Annali di Elettricita Medica e Terapia Fisica*, February, 1904.

Epilepsy; Pathogeny and Therapeutic Indications.—Alexandre Paris declares that epilepsy is the expression of a disproportion between the original constitution, from the point of view of the sensitiveness and susceptibility of the cerebral nerve centers, and their habitual stimulants emanating from the glandular organs, whose function is that of reproduction—the ovaries or testicles, which not only assume reproduction by the association of their secretions, but which by a certain stimulating effect on the nerve centers, forming to a certain extent the complement of the function of the thyroid body, foster reproduction. When the functional activity of these glands is too great, or the elimination insufficient, that is, when the accumulation is abnormal, the result of the action of exciting products in the nerve centers will be an epileptic manifestation, if these centers have a special susceptibility which might be termed an epileptogenous constitution. Thus considered, the writer thinks the pathogeny very simple. The ends to be attained in treating epilepsy are: to diminish cerebral excitability; to moderate the functional activity of the thyroid gland especially, and that of the genital glands; to assure the regular elimination of their secretions by preventing their accumulation in the organism; to prevent all causes of excitement, such as the accidental accumulations of toxins. The writer's results in the treatment of epilepsy have been excellent.—*Archives de Neurologie*, March, 1904.

A Case of Typhoid Without Any Grüber-Widal Reaction.—C. Battignani reports a case of typical typhoid, with all the classical symptoms of high continued fevor, bowel disturbances, delirium, and heart weakness, in which there was at no time any Grüber-Widal reaction to be obtained. Malarial infection was excluded by blood examination. The spleen was enlarged, there were a characteristic roseola, diarrhœa, and ileocæcal gurgles. The blood was tested daily even during convalescence, but no reaction was ever obtained. In the examinations for the bacilli, a bacillus was found that resembled exactly Eberth's bacillus.—*La Riforma Medica*, March 2, 1904.

Sclerosing Epithelioma of the Right Lower Eyelid Resection of the Whole Eyelid with Autoplastic Operation.—Morax reports this case. The interesting points are, first, the age of the patient, who was only twenty-seven years old. The type of tumor—that form of cutaneous epithelioma which gradually extends, but heals partly as it goes by the production of cicatricial tissue is seen in the middle-aged and later, but is rare at the age of twenty-seven. The evolution of this lesion was extremely slow, for after ten years the entire surface of the eyelid was not involved. On the other hand the recurrence was very rapid. For one month after the first intervention regulations developed which were larger than the cutaneous epitheliomatous nodules. An extensive dissection was then made and the lower lid replaced by an autoplastic operation. No recurrence has taken place since.—*Pecueil d'Ophtalmologie*, February, 1904.

The Hydroelectric Bath and Disturbances of Pregnancy.—Giulio Moglie believes that the hydroelectric bath is one of the best remedies for the cure of many nervous maladies and especially of those that result from changed organic conditions. He has experimented with the disturbances of pregnancy, especially those referred to the stomach. He cites four cases of severe vomiting of pregnancy, one in which life was threatened by the inability to take any nourishment. In these cases electric baths were used with excellent results. In each case, after about ten baths, there was complete and permanent relief from the nausea and vomiting, return of appetite and a perfect normal digestion. He considers it demonstrated that this treatment is an excellent one for disturbances of this kind in the pregnant woman.—*Rivista Internazionale di Terapia Fisica*, March 1, 1904.

Acute Diffuse Hepatitis with Icterus Gravis in the Course of Secondary Syphilis.—Armand Siredey and Henri Lemaire state that although jaundice is often noted in the course of secondary syphilis, nevertheless icterus gravis is exceptional. Fournier cites only about twenty-five cases. The writers then mention a case in point. The patient was a girl of eighteen years, showing a secondary syphilitic eruption. Suddenly delirium developed and the patient finally fell into a comatose condition. The patellar reflexes were exaggerated; there was generalized hyperæsthesia, and dilatation of the pupil. Abundant biliary pigments and albumin appeared in the urine. The liver was rather diminished in size. Death occurred about thirty hours after the patient's entrance to the hospital. At autopsy diffuse hepatitis was found with progressive destruction of the cells coincident with diffuse peri-cellular sclerosis.—*Journal des Praticiens*, March 12, 1904.

The So-called Pericarditic Pseudocirrhosis of the Liver.—Ferruccio Schupfer illustrates the subject by a case under his care, which came to autopsy after two years of observation. There was total adhesion of the pericardium, calcareous pleurisy of the right side, adhesive pleurisy of the left; perilobular cirrhosis of the liver, perihepatitis, ectasia of the hepatic veins, left crupous pneumonia; recent fibrinous peritonitis. There was marked ascites, effusion into the pleural cavities, an enlarged liver and spleen and chronic kidney disturbances, as well as heart symptoms. After comparing his cases with those reported by other writers, he closes with the following conclusions: (1) In patients with pericardial adhesion you may have the common picture of asystole, with a marked ascites simulating hepatic cirrhosis; (2) In one form of case you may find a small amount of ascites, associated with œdema of other parts of the body; (3) When ascites is abundant and not accompanied by œdema in other parts, it may be of different origin; very rarely it may arise from hepatic cirrhosis of cardiac, alcoholic or tuberculous origin. In most cases it is due to a chronic peritonitis, slowly progressive; (4) In regard to the cause of the ascites great weight must be given to the alteration in the capsule of the liver and the central tendon of the diaphragm. (5) In the author's case there was a polyserositis, slow, subacute and progressive; (6) Even when cirrhotic lesions exist, whether of cardiac origin or capsullar ascites is not always the result, provided it leaves a normal caliber to the vessels of the liver.—*La Riforma Medica*, March 2, 190

The American Journal of the Medical Sciences, February, 1904.

A Fatal Case of Poisoning with Oil of Gaultheria.—J. Woods Price and Edward M. L'Engle report this case. The patient was a girl aged two years. She had swallowed about a drachm of commercial oil of wintergreen. She had vomited several times, and continued to do so until lavage could be done. There was nothing abnormal in the child's appearance, and she showed no evidences of suffering pain. There were no further symptoms for two hours, when the patient seemed to have pain in the abdomen, was drowsy, and complained of great thirst. The pulse rate increased to 150. The respirations became somewhat labored and irregular and there were evidences of impaired hearing and some hallucinations of vision. Later, convulsions took place, the symptoms increased in severity, and the child died of respiratory failure, ten hours after the ingestion of the poison.

A Case of Seborrhœa Nigricans (Black Mask of the Face).—Arthur Van Harlingen reports this unusual case. The patient was a girl of twenty-three years who had been bedridden for several years. Her general condition was that of an hysterical person. No areas of insensibility were disclosed, but the scalp was hyperæsthetic. The forehead and nose were covered with an extraordinary mask or crust, more than quarter of an inch thick, resembling a slice of ham—soft, greasy, sharply defined about the edges, and rounded. It could be easily broken off, and the forceps could be thrust in at any point as if the crust were comprised of soft fat. The color of the crust was exteriorly of an inky blackness. The attendants were instructed to wash the mask daily with a solution of sapo viridis in water. At the end of a week, however, the mask had not been at all cleaned off. It was loosened, and there was no difficulty in stripping off the entire coating. The writer believes this to have been a severe case of oily seborrhœa, giving rise to a dusky secretion upon the surface. This had been allowed to accumulate for several years, and had perhaps been added to by the application of ointments, together with accretions from the surrounding apartment.

A Case of Typhoid Fever Presenting an Arterial Complication—Probably an Arteritis.—Walter R. Steiner reports this case. The patient was a boy of nine years suffering from an attack of typhoid fever. On the evening of the forty-first day, he complained of numbness and tingling of the right index-finger. There was no difference between the right and left radials. On the following day the right radial pulse was distinctly smaller in volume than the left, but differences between the axillaries and brachials could not be made out. On the day following, the pulse was wanting in the right radial, brachial, and axillary arteries. Much pain was complained of on palpation, and the axillary and radial arteries had a hard, cord-like feel. The right arm was colder than the left, and there was some blueness of the finger-nails. The arm became extremely cold and the finger-nails intensely cyanotic. The patient's condition became desperate. But gradually he began to improve, and thirty-five days after the onset of the arteritis there was noted a return of pulsation in the right radial and brachial arteries. In three days there was no difference between the two sides. The writer regards the arterial complication as one of the peripheral arteritides.

The Nervous Complications and Sequelæ of Smallpox.—Charles T. Aldrich declares that smallpox, like other infectious diseases, may present various nervous complications and sequelæ. Almost the first effect of the variolous poison is observed in the violent frontal headache, which instantly is an early symptom. These affections may be gross anatomical, purely functional, or both. They include all possible provinces of the nervous system—the brain, spinal cord, and peripheral nerves. At least four types of the febrile deliria and psychoses are recognized; initial delirium, febrile delirium, collapse or exhaustion delirium, and true post variolous insanity. True dementia paralytica has been observed to follow variola. Meningitis is a rare complication. It is usually purulent, and probably a metastasis from the skin lesions. The occurrence of paralysis in smallpox has been commented upon. Areas of simple softening and blood extravasations may occur in the brain and produce aphasia, monoplegia, or hemiplegia. The relative frequency of cord affections in variola has long been known. The writer believes that a disseminated encephalomyelitis occurs as a complication or sequel of smallpox, which possesses clinical features and pathological changes entitling it to be recognized as a clinical entity. The writer has found fifteen cases in the literature. He concludes by giving a report of various cases.

Circumcorneal Hypertrophy (Vernal Conjunctivitis) in the Negro.—Swan M. Burnett states that the distinguishing mark of circumcorneal hypertrophy is that it is not destructive. It is a true hyperplasia. Identical changes in the conjunctiva of the lid have been revealed. Hypertrophy is everywhere, but destruction of tissue is nowhere found. The usual and characteristic complaint is not of pain, but of an intense itching of the eyes and sometimes of a "burning sensation," quite distinct from the subjective symptoms of phlyctenulæ. The objective appearance is strikingly distinctive. The dirty gray elevations at the base of the cornea, when marked, bear no resemblance to any other pathological condition found there. The circumcorneal epithelial changes vary greatly in degree. Some lacrymation may occur, but the irritative symptoms are slight. In this disease the palpebral aperture has a dull, soggy look, and a dusky appearance, as though it had been smoked. The cause of this peculiar appearance is a pigmentation of the conjunctiva. The writer believes that both the bulbar and palpebral forms exist together. He also believes that the disease is the manifestation of a dyscrasia—but it is not so certain what that dyscrasia is. Although "scrofula" can never be excluded in a colored patient, still there is nothing about the appearance of the condition itself or in the patient's which would justify the acceptance of any such stigma as a cause. It occurs often in the most robust looking. The disease is most prevalent during the hot months. Strictly speaking, the affection is not a conjunctivitis at all, taking conjunctivitis to mean an inflammation of the conjunctiva. The similarity of the disease to trachoma is only superficial. As to treatment, the indications are for palliative local measures. Operative measures are not advisable. Attention to nutrition and an improvement in the general condition are called for. Most authorities approve of the administration of arsenic in some form.

A Discussion of the Surgery of Tumors of the Brain, with a Résumé of the Operative Records of Four Craniotomies.—Charles H. Frazier sums up his paper as follows: (1) All measures recognized as prophylactic of shock should be observed stringently. In these we have the most effectual means of reducing the mortality. The most important of them are (*a*) the avoidance of prolonged operation; (*b*) the prevention of excessive hemorrhage, and (*c*) the avoidance of unnecessarily rough manipulation of the brain substance. (2) A given area of brain can be exposed with the least minimum degree of traumatism and greatest economy of time by the electric engine. (3) Temporary closure of the carotids in operations upon the brain is effectual and not unattended by danger. It should be reserved for extreme cases, and practised on one side only. (4) Observations should be made upon the blood-pressure immediately before and at frequent intervals during the operation. Object of same twofold: (*a*) as the most reliable index of patient's condition; (*b*) as the only exact method of determining whether operation should or should not be carried out in two stages. (5) Two-stage operation is indicated when there has been a decided fall in blood-pressure after the relief from intracranial tension, such as follows reflection of the Wagner flap and dura. (6) Lumbar puncture as a means of relieving pressure is a temporary, not to say dangerous, procedure. (7) Bulging of the brain is one of the most embarrassing features of cerebral operations. A distinction may be made between that which occurs immediately after reflecting the dura, "initial" bulging, and that which follows as a result of subsequent exploratory manipulation, "consecutive" bulging. (8) "Initial" bulging is due to the increased tension exerted by a tumor. It is not always present, is often not excessive, and is not likely to be followed by "consecutive" bulging. (9) "Consecutive" bulging is due to the cerebral œdema set up in normal brain tissue by trauma inflicted by the exploratory manipulations. "Consecutive" bulging far exceeds in magnitude initial bulging, and suggests the absence of a tumor of considerable size at the seat of operation. (10) In order to avoid this "consecutive" bulging, which is a most embarrassing feature of these operations, exploration should be carried out in the most expeditious manner. (11) When the edges of the dural wound cannot be approximated without undue tension or without great laceration of brain substance, the gap should be closed by a graft taken from the pericranium, providing the tumor has not been found and there is reason to question the accuracy of the diagnosis. (12) When there is every assurance of a tumor being present, but it proves to be inoperable or was imperfectly localized, no attempt should be made to close the dura, as in so doing the best possible palliative effects of the operation would be counteracted. (13) Palliative operations should be regarded not merely as operations of propriety, but should be considered imperative whenever the tumor cannot be found or cannot be removed. (14) A statistical study of the results of the last five years is encouraging. The mortality, both immediate and subsequent, has been reduced materially. Recurrence after operations for malignant growths of the brain is no greater than after operations for malignant growths of other structures.

Book Reviews.

THE INTERNATIONAL MEDICAL ANNUAL: A Year Book of Treatment and Practitioner's Index. Twenty-second Year. New York: E. B. Treat & Company, 1904.

THE 1904 edition of this volume—the twenty-second annual—is an excellent index of the literature of the past year. The editors have given preference to the practical work that has been accomplished. A new departure in this volume consists in the stereoscopic views that have been introduced. The examination of these with the little instrument provided, greatly facilitates the study of structures which by other methods are very difficult to illustrate. The section devoted to diseases of the ear is specially illustrated by a set of twelve stereograms. There is a series of plates representing the distribution and nature of the eruption in certain of the infectious diseases such as smallpox, scarlet fever, measles, typhoid and typhus fevers. The text is compact, and has been kept within moderate dimensions. In this way the real value of the book is undoubtedly enhanced. The literature of the past year so teems with new matter that this annual is correspondingly interesting. The sections on serum therapy, radio-activity, and electro-therapeutics represent a great deal of careful observation. Although in the past year no great discovery in therapeutics has been made, nevertheless the number of new synthetic remedies has been maintained. Several new hypnotics and analgesics are now on the market, most of which are still on trial. The present volume compares well with its predecessors.

ATLAS AND EPITOME OF OPERATIVE GYNECOLOGY. By Dr. OSKAR SCHAEFFER, Privatdocent of Obstetrics and Gynecology in the University of Heidelberg. Authorized Translation from the German with Editorial Notes and Additions. Edited by J. Clarence Webster, M.D., Edin. F.R.C.P.E., F.R.S.E., Professor of Obstetrics and Gynecology in Rush Medical College. With 42 colored Lithographic Plates and many Text Illustrations, some in colors. Philadelphia, New York, London: W. B. Saunders & Company, 1904.

THIS is a fitting companion piece to the "Atlas and Epitome of Gynecology" by the same author that preceded it in this series of beautifully executed atlases. The plan is much the same as that followed in the volume devoted to pathology and diagnosis, viz., short sections of text discuss very concisely the important topics and the accompanying plates elucidate the letter press. Short paragraphs opposite the plate serve to point out the significance of the features illustrated. The method is a good one, and is carried out with such attention to detail that the volume should prove most helpful to students and others in grasping details usually to be acquired only in the amphitheater itself. The technique indicated is of course essentially continental and differs in some respects from that practised in this country, but the frequent paragraphs of editorial comment serve to discount this drawback.

HOWE'S HANDBOOK OF PARLIAMENTARY USAGE. Arranged for the instant use of Legislative and Mass Meetings, etc. By FRANK WILLIAM HOWE. New York: Hinds and Noble, 1904.

BY an ingenious method of graduating the length of the leaves the "rules of order" are so arranged as to be available for instant reference.

MEDICAL UNION NUMBER SIX. By WILLIAM HARVEY KING. New York: The Monograph Press, 1904.

WE heartily wish for this clever little book a widespread dissemination. In a most humorous, but at the same time keenly satirical, manner it points out the weaknesses of trades unionism by depicting conditions supposed to exist in the middle of the century. Even the doctors and clergymen have organized, and through strict adhesion to the rules of unionism the country is depopulated and ruined.

ELÉMENTS DE PATHOLOGIE ET DE CLINIQUE CHIRURGICALES. Par le Dr. LÉON MOYNAC (de Bayonne). Ancien Interne des Hôpitaux de Paris. Ancien Professeur Libre de Pathologie et de Clinique. Huitième Édition, en trois tomes. Paris: G. Steinheil, 1903.

IT must be admitted that this work on surgical pathology and treatment suffers greatly on comparison with more recent American treatises. The illustrations are crude wood cuts, the paper and print are poor, and nowhere do we see any of the devices to attract readers that are so abundant in modern books. Yet the fact that this is the eighth edition stands for a more than passing popularity, and on closer examination it does not seem so strange that it should have made many friends. The work is really a *multum in parvo*, almost encyclopedic in its comprehensiveness of scope, which covers all the theory and practice of surgery as ordinarily understood, together with such specialties as the eye, ear, nose, throat, etc. In its method of treatment the work stands midway between our quizz books, which it far surpasses in point of completeness, and particularly in evidence of the author's practical experience, and the larger treatises which its diffuseness prevents it from equalling. The first volume is devoted to the general principles of surgery and the surgical pathology of the tissues, the second to regional surgery, comprising the head, chest, abdomen, and extremities. The third volume is concerned with the ear, larynx, eye, genitourinary tract, and gynecology. All of these subjects are treated with a most agreeable vivacity of style, which does much to cause one to overlook the lack of freshness in some of the views expressed. In short, it is a relic of the days when one man could and did cover the whole domain of surgery in his teaching and practice and is well adapted to the needs of the student who requires condensed information. It has little value, however, for non-gallic readers, except as a mirror of the old surgical methods of its country of origin.

GESAMMELTE ARBEITEN ZUR IMMUNITÄTSFORSCHUNG. Herausgegeben von Professor Dr. P. EHRLICH, Geheimer Medicinal-Rath. Mit 12 Figuren. Berlin: August Hirschwald, 1904.

THIS volume of nearly eight hundred pages will no doubt be most gratefully accepted by laboratory workers all over the world. It comprises the most important of the papers on immunity and kindred subjects which during the last four or five years have eminated in such profusion from the laboratory of Ehrlich. It comprises thirty-eight essays, of which about a third are the work of Ehrlich alone or in collaboration, and the others are mainly by his most prominent disciples, such as Morgenroth, Neisser, and Sachs.

Although the side-chain theory has now been officially recognized at nearly every scientific court, there are still some opponents of Ehrlich's views, and one of the most interesting papers in the book is the very last in which Ehrlich defends himself against the attacks which Gruber lately directed against him. Each step in the building up of the theory, together with its underlying experimental evidence, is given with masterly clearness, and the papers forms an excellent means of gaining an understanding of the intricacies of this complex subject. Two other communications of great practical value are those by Morgenroth and Neisser dealing with the technique of studies in hæmolysis and bacteriolysis, and which were written especially for this volume.

The collection forms a most useful work of reference which will be found almost indispensable by workers in this field.

LECTURES ON DISEASES OF THE NERVOUS SYSTEM. (Second Series.) By Sir WILLIAM GOWERS, M.D., F.R.C.P., F.R.S. Philadelphia: P. Blakiston's Son & Co., 1904.

THIS series consists of ten lectures that have been revised for publication. The subjects are as follows: (1) Subjective Visual Sensations. (2) Subjective Sensations of Sound. (3) Abiotrophy; Diseases from Defect of Life. (4) Myopathy and a Distal Form. (5) Metallic Poisoning. (6) Syphilitic Diseases of the Nervous System. (7) Inevitable Failure. (8) Syringal Hemorrhage into the Spinal Cord. (9) Myasthenia and Ophthalmoplegia. (10) The Use of Drugs. These lectures will not fail to prove instructive reading to those interested in neurological literature. That on "Abiotrophy" (an original term by the author) is of exceptional interest, for it helps to elucidate a class of diseases, such as idiopathic muscular atrophy, the various myopathies, and primary degeneration of neuron systems, as being due to failure of nutrition from an inherent defect in vitality. The other lectures are equally valuable and bear evidence of wide clinical experience and close observation.

A TEXTBOOK UPON THE PATHOGENIC BACTERIA, for Students of Medicine and Physicians. By JOSEPH McFARLAND, M.D., Professor of Pathology and Bacteriology in the Medico-Chirurgical College, Philadelphia; Pathologist to the Philadelphia Hospital and to the Medico-Chirurgical Hospital, Philadelphia; Fellow of the College of Physicians of Philadelphia, etc. Fourth edition. Philadelphia, New York, London: W. B. Saunders & Company, 1903.

THE student of bacteriology is at no loss in these days for textbooks. New books and new editions of older books are continually dropping from the presses, but there must be no lack of purchasers, else the shower would cease. The truth is there is so much activity in this young science that every new writer has something new to say and so his book has value. The work before us is not a general treatise on bacteriology but deals only, or chiefly, with the pathogenic bacteria; nevertheless, it contains much useful material on bacteriological technique as well as hints on laboratory methods. In this new edition the author has brought the whole book thoroughly up to date.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held March 17, 1904.

DR. ANDREW H. SMITH, M.D., IN THE CHAIR.

ns meeting was held under the auspices of the section ophthalmology.

Presentation of Portrait of Ex-President Robert F. Weir. Dr. Jos. D. BRYANT said that it was indeed a welcome vilege for him to be permitted to speak of a friend on an asion of this kind. Under these circumstances one was lined to tell of the professional attainments of the nd, and under all proper surroundings one should clare the friend's loyal adherence to probity and to his n friends, speaking also of his kind and genial nature, r shedding its sunshine, without shadows, on all who ne within the sphere of his influence. If the entire fession were here he said it would be a supererogation his part to recite the achievements of their much-pected Fellow in the field of his choice. For along the away of surgical endeavor, both at home and abroad, nearly a quarter of a century were frequently noted l-recognized and enduring evidences of Dr. Weir's ughtful and beneficent labors. His teachings, his tings, and his practical illustrations in surgery had ever n constructive, and his ideas of surgical problems and rgical policies were both wise and refreshing. Fitting, ed, was it that the excellent likeness of their friend uld be made fast to the wall of the Academy, near portraits of those who were pioneers in the art ich their esteemed Fellow so aptly graced—Valentine tt, Van Buren, Hamilton, and Wood. While they dly did him honor at this time, he asked that they be unmindful of the fact that already he had been ly honored abroad. It was not at all strange, he ought, that one who had attained well-grounded inence in a special field of thought or effort, requiring r the purpose earnest actions based on honest con-ptions, should be alike loyal to wholesome principles and wholesome friends. If this was true, then Dr. Weir's ributes in these respects were but the logical heritage an honest heart. His genial greeting, his warm, ndly grasp of the hand, and his frequent verbal con-ts were like unto summer showers, delightful and re-shing, serving equally to lighten his own burdens and to en the stress of those of his Fellows. He said that were here at that moment, might he not properly exclaim, n speaking of Dr. Weir, please, sir, do not longer weary e indulgent listeners?" Therefore, heeding this im-native admonition, he humbly requested, through the sident, that the Fellows of the Academy accept the ness of the late President, Dr. Robert F. Weir, and ce it where it would ever be an earnest to all whose rthy ambitions might prompt them to emulate the ny virtues of him whom that work of art so well rtrayed.

Dr. ANDREW H. SMITH then graciously accepted the rtrait in behalf of the Fellows of the Academy.

Subject of the evening: "The Eye in Its Relation to nctional Nervous Disease."

Mental Disturbances Produced by Eyestrain.—Dr. C. L. ANA read this paper. He said that the term "eyestrain" as not found in works on psychiatry and was not men-ioned at all in recent works on ophthalmology. The eye eemed to be the only organ which was popularly as-ociated with strain, and as a convenient word it probably carried a definite meaning to most minds. Eyestrain was of two varieties: (1) An automatic effort of the brain and oculomotor nerves to adjust the eye so as to overcome abnormalities in refraction and accommodation and im-perfect muscular balance. This was largely done un-consciously and was a kind of spinal eyestrain. (2) The eyestrain that occurred when the eye was more seriously defective and the receiving apparatus of the brain fatigued. Then the cortical centers were brought into play and the imperfect vision was appreciated with some sense of a distinct and fatiguing effort to supplement the ordinary automatic mechanism of the eye. This effort was not recognized as an effort for better vision, but simply as something wrong. This kind of an eyestrain was really a brain strain and was the only kind of a strain that could do any harm. Most minor ocular defects could exist without doing any harm, the organ compensating perfectly like a leaky heart. Psychoses might also be divided into two groups—insanity, technically speaking, and minor psychoses, as hysteria, neurasthenia, mild melancholia, etc. Alienists, without exception, did not recognize eyestrain as a factor in producing major psychoses, and in fact did not even refer to it. He cited several attempts that had been made in State hospitals by competent oculists to cure or help cases of insanity by treating the eyes, but without success. He had been watchful for eye defects in psychoses and neuroses and had investigated Dr. Steven's views in regard to eyestrain in epilepsy and chorea, but had seen only a few cases of eyestrain with bad results mentally, and these were in secondary schools where the young men worked very hard. It seemed as though the eyestrain in these cases led to a kind of exhaustion psychosis. In only one of these cases was the exhaustion so prolonged and so marked that there was danger of dementia præcox. Nevertheless he considered it wise to have the eyes of psychopathic children examined. In men in the forties who do hard clerical work, presbyopia might come on insidiously, and produce a condition of mental depression and irritability, but these cases were rare. After twenty years of careful watching he had found hardly any cases in which eyestrain was an important or direct factor in establishing even a minor psychosis, though it might modify symptoms and add to the disturbance. Dr. Gould gave sixty-eight reasons why success is not generally attained by treating the eyes in these cases, and he could add that success was generally obtained without treating the eyes. When the mind is a good mind, the visual machinery does not overthrow or seriously affect it. He would be sorry to believe that our mental balance and nervous well-being were so entirely at the mercy of slight defects in an organ that had been perfected by centuries of use and misuse. Happily there was, as yet, no such a psychosis as visual hypochondria. Civilization was making us use our eyes more and more in near vision and psychoses were increasing, but these conditions had not as yet led to any more alarming results than the extraordinary prevalence of glasses and the spectacular success of opticians. Glassing was enormously overdone as well as underdone and had become in a way a real psychosis.

Headache, Migraine, and Other Sensory Disturbances Produced by Eyestrain.—Dr. C. W. CUTLER read this paper and said that migraine was considered by most writers clinically as a paroxysmal neurosis, having as its chief symptoms headache and a variety of sensory phenomena, characterized also by heredity, periodicity, and commencement in early life. He suggested that migraine or sick-headache was a manifestation of an unstable nervous organism, influenced in many cases by various peripheral excitations, and that these, or rather their anatomical bases, were frequently transmitted from one generation to another in members of the same family, and formed the hereditary feature upon which stress had been laid as an essential characteristic of migraine. It was evident that the periodic attack could not characterize migraine, for periodicity did not exclude the constant cause. In Jacksonian epilepsy the cause was constant when it followed a fractured skull, for instance, although the symptoms were in the highest degree periodic. Migraine occurring in families was handed down with direct inheritance, and it was relatively uncommon to find any variation of the type of disease, such as alternation in epilepsy, in other members of the family. It was often

strikingly similar in detail in different members of the same family. The fact that ocular defects were handed down in families with great uniformity was a common experience. Putting these facts together, the heredity of migraine of a fairly constant type with the transmission of certain forms of ocular defects in members of the same family, the correction of which in some cases relieved the sick-headache, and we had a fair basis for the assumption that sick-headache, having all the clinical features of migraine, was often a reflex neurosis of ocular origin. No doubt there were many other sources of peripheral irritation—the pelvic organs, the nose, the digestion, which, however, need not be discussed here. The question raised was this: Where no peripheral factor in the etiology of sick headache was apparent, was not the fault in our defective means of diagnosis? The two obstacles to a solution of this question were a mistaken or confused idea of migraine, and imperfect methods of diagnosis. Many cases in which headaches occurred, which were indistinguishable clinically from true migraine, and could only be differentiated from it by the fact that they followed some peripheral cause, and were removed when that was removed. But those who suffered in this way were subject to attacks from irritations disproportionately small. Thus, when a patient had sick-headache and was cured by correction of ⅛ d. of astigmatism, the fault was not with the eyes, primarily, but with the unstable nervous organism which made him susceptible, and this was what migraine resolved itself into. But the fact remained that the disease must be approached at the periphery, and with more hope of success as our diagnostic and therapeutic measures became more perfect. There were, no doubt, many cases of migraine which were or had become inveterate, and we were tempted to accept the visitations as inevitable, and limit the treatment to the attacks. This attitude was to be regretted, as it was possible, in many of these cases, as a more perfect knowledge of their nature was acquired the conception of hereditary migraine would be modified, and it would be recognized as a reflex neurosis, consisting of an unstable organism, excited by certain peripheral strains which formed the hereditary influence. The chief danger in the passive acceptance of the idiopathic idea was that thereby all effort was abandoned to determine the excitable and removable factor in the etiology. Migraine should be studied statistically, not only with regard to its prognosis and results of treatment, but as regards its natural history; and data, to be valuable, must contain information regarding family history and the family anomalies of structure, as well as the character of the attacks and the relation to the kinds of strain.

The Relation of Epilepsy, Chorea, and Other Motor Disturbances of the Nervous System to Eye Disease.—Dr. B. Sachs read this paper. He said his part in the discussion was limited to the consideration, chiefly, of the bearing of ocular disturbances upon the development and occurrence of epilepsy, of chorea, and of the convulsive tics. He believed that the dependence of these motor neuroses upon disease of the eye had been greatly exaggerated. It was curious that the claim of the relation of ocular affections to epilepsy and chorea was mainly maintained by American writers, by oculists and pseudo-oculists rather than by neurologists. All who were competent to discuss the subject of epilepsy were agreed that it was a serious chronic affection of the nervous system due to some deeply rooted changes, and the effect of such changes became manifest early in the life of the individual. If one wished to prove that epilepsy was due to some disturbance of the eyes, he said, the argument must rest upon evidence that such ocular disturbance had existed as long as, if not longer than, the epilepsy itself, and that with the correction or cure of the ocular affection, the epileptic attacks would cease. From an argument he put forth, the just inference was that if the epileptic patient presented any marked physical disturbance, whether it be a nasal obstruction, a narrow prepuce, a discharging ear, or other physical disturbance, let that condition be remedied, for it might be the exciting cause of the individual epileptic attack; but he asked them not to suppose for an instant that the existence of such physical condition was the actual cause of the epilepsy. From his personal experience he did not know of a single case in which the epileptic seizures had been altogether inhibited or even diminished in number by the wearing of glasses, by the cutting of muscles, or by any other ocular measures which had been adopted.

He said that what had been said regarding epilepsy would apply with equal force to the relation of eyestrain and other ocular disturbances to chorea minor, or St. Vitus' dance. The idea that St. Vitus' dance might be due to some slight lack of adjustment in the ocular apparatus was too absurd to be considered.

There was another disease entirely distinct from St. Vitus' dance, but which bore a superficial resemblance to it and which might sometimes be caused by eyestrain, and this was the condition known as habit chorea, characterized in some by blinking of the eyes—in fact, by all forms of grimaces, by irregular movements of shoulders, of the hands, of the feet, etc. In such cases it would be well to have the ocular apparatus carefully examined, as well as the nasal condition, and any existing defect, however slight, should be remedied.

In summing up all that possibly could be said with due regard for truth, it might be stated that the relationship between ocular affections and epilepsy, chorea, and convulsive tic might be a close one in the minds of some faddists, but it must remain a very remote one in the minds of those who have no special axes to grind and no special therapeutic territory to exploit.

The Eye Symptoms of Hysteria, Neurasthenia, and the Traumatic Neuroses.—Dr. Ward A. Holden read this paper. He said that since the functional eye disturbances in hysteria and neurasthenia were not always characteristic of one condition or the other and the disturbances of traumatic neurasthenia did not differ from the non-traumatic varieties it was not necessary to classify symptoms according to the underlying neuroses or psychoses. The morbid states which gave rise to these symptoms were: (1) The cornea and conjunctiva might be anæsthetic or hyperæsthetic. (2) The eye muscles might be relaxed from fatigue or might be in a state of spasmodic contraction. (3) The visual perceptive apparatus might show signs of fatigue and there might be psychical perversions of visual perceptions. The subjective symptoms were pain and paræsthesia in various parts of the head after using the eyes, clouds or bright spots before the eyes, and apparent increase or decrease in the size of objects looked at. The print might fade away because the muscles of accommodation had relaxed from fatigue, or it might be doubled because convergence could not be maintained, or the print might flutter or become confused because of the abnormally prolonged duration of after-images in the retina. When the lids were gently closed a fine tremor was always noticed. There might be lacrymation, and also photophobia. Complete forcible closure of one or both eyes from tonic or clonic spasm of the orbicular muscle might occur. The reflex closure when the cornea or conjunctiva was touched might be slow or wanting, indicating anæsthesia. The pupils were usually normal in size and reaction. The extraocular muscles often exhibited a lack of balance or exaphoria. A spasm of any of these muscles might give rise to diplopia, but this might be distinguished from actual paralysis by the anomalous behavior of the double images in different directions of the gaze, and the presence of corroborative symptoms. Uniocular diplopia of a purely psychical nature was absolutely characteristic of hysteria. The acuteness of vision in these cases was usually normal, but the patient read slowly and apparently with great effort, often only after much urging. Blindness of one or both eyes might be simulated. Anomal-

s of the visual fields were the most frequent and characristic eye disturbances in neurasthenia and hysteria. he typical condition was a normal field for the usual hite-test object and a concentric contraction of the color elds in their regular order with a diminution of central olor perception. Beside the typical concentric conaction of the color fields in their regular order there was ccasionally a reversal of the sequence, but rarely was ere a central defect in the field or a defect of a hemianopic ype. The size of the fields varied from time to time. he forms of the color fields in hysteria were sometimes so arre that they did not simulate any organic lesion. hough a number of cases of functional eye disturbance young women were cited the trouble was by no means nfined to this class. Some of the most marked and nsistent disturbances were found in strong men with steria following injury or nervous shock.

Dr. G. E. DE SCHWEINITZ of Philadelphia was interested what Dr. Dana said regarding melancholia. He ought it was a condition frequently encountered, parularly among middle-aged school teachers who went o the choreas and states of mental depression. He lieved that Dr. Dana's description of the disturbances of ntality from eyestrain was correct. Certainly many es were seen in the so-called backwardness occurring children; when the eyestrain was corrected the mental ndition became better, and this was a point already well ognized in schools for training where the correction eye defects was gone into carefully. His neurologist nds had stated this to be a trifling affair, but he said was the trifling errors which produced these troubles. was the constant effort to correct small faults which re out the nervous mechanism.

He was glad to hear Dr. Cutler's description of migraine. never thought he could cure a true case of migraine any correction of refractive errors, although he might sen the number of attacks, because the condition was e sometimes caused by peripheral irritation.

He agreed with what Dr. Sachs had stated and he had ver seen a case of chorea cured by glasses. He believed ough the correction of any error of refraction by glasses uld be a part of the treatment, same as the removal of noids, etc. This same was true of epilepsy. He was d to hear such a firm stand was taken by many on the nservative side of the question.

In referring to Dr. Holden's paper he said that bilateral aurosis in hysteria was not a common symptom, some- ng like fifty cases only being reported, and these were es of absolute blindness. So many of the cases apared suddenly and lasted for a few minutes, or a few urs or, in exceptional cases, days. There had been reted intermittent hysterical amaurosis occurring in a w. In hysteria there might occur concentric contracons in the visual field which was sometimes referred to as tubular field. Hemianopsia he said was a subject much itten about, some saying that they never saw a case in steria and others saying that they never saw a case thout its presence. He believed that in a certain numr of hysterical amaurosis, bilateral or unilateral, there as a period of hemianopsia that occurred between the ppearance of the amaurosis and the appearance of rmal vision. Sometimes when the amaurosis appeared rly, with a central scotoma would often be found hemiopsia and restoration of the visual field.

Dr. JOHN E. WEEKS continued the discussion, giving the sults of his clinical observations. He said there were wo lines of experimentation: first, of the results which llowed more or less complete relief of eyestrain by the rrections of the errors of refraction; and second, obsertions on the mental disturbances which occurred as the sult of eyestrain due to malcorrection of errors of reaction and malcorrection of errors of muscles. His remarks were based on observations of such cases.

No cases of migraine had been cured, but the number of ttacks had been lessened by the correction either of errors of refraction or errors of muscles. Many mental disturbances had been relieved by treatment of eye conditions, and headaches of certain varieties might be permanently relieved, as well as vertigos of certain varieties, etc. Certain functional nervous disturbances might be relieved in cases of facial spasms, and in which, certain eye muscles were totally or partially affected in one or both eyes. He thought that the motor nervous disturbances which might be modified by attention to the eyes were chorea and some cases of epilepsy.

Dr. JOSEPH COLLINS said that after fifteen years' experience he had never encountered a frank mental disease which itself could be in any way attributed to an anomaly or defect of the eye or muscular apparatus of the eye. The melancholic conditions mentioned occurring at the ages of forty or fifty years he presumed should be looked upon as marked involutional melancholias, and here the eye condition should be considered as an effect rather than a cause of the mental state. Regarding the condition of the eyes found in backward children it seemed to him that this was susceptible of an easy explanation. There were many children whose educations were hampered and intelligence retarded by certain conditions which went without saying; for instance, if they could not get books they were retarded, and if they could not get glasses then too were they retarded. So far as he could see, no cases of dementia præcox, or involutional melancholia were in any way genetically related to the eyes. There was no relationship between eyestrain and the cure of epileptics. One case out of sixty-seven had been benefited at the Craig Colony by attention to the eyes.

So far as chorea was concerned, he did not think it should be discussed at all, because he did not doubt but that it was caused by a microorganism, the same that produced polyarthritis. When the microorganism of chorea was found he believed it would be found to be the same that caused polyarthritis. In looking through the statistics of a large number of cases of migraine one would not find even one case that had been cured, remedied, or benefited by the adoption of glasses. But, on the other hand, he knew of a number of cases of pseudo-migraine that had been cured by the adoption of proper glasses. Migraine and pseudo-migraine were as different as paresis and pseudo-paresis. True migraine was a true neurosis and was due to a lack of proper and harmonious development dating back for years.

Dr. W. P. MARPLE related some interesting cases that had occurred in his experience.

Dr. HERMANN KNAPP said that eyestrain was due to overexertion of the eye. The eye could be overtaxed the same as any other organ. If the eyes are overtaxed the individual must wear glasses or suffer the consequences; and these consequences will be shown possibly in any weakened spot in the body. It may show itself in the nervous system, or in the circulatory system or elsewhere, wherever there is a weakening of a part.

Dr. ANDREW H. SMITH reported the case of amaurosis occurring in a very nervous woman who lived unhappily with her husband, and who strongly opposed her doing what she wished one evening. In a brief time she became absolutely blind and continued to be so for thirty-six hours. The pupils were moderately dilated and fixed.

He also reported a case of migraine occurring in a woman. The attacks occurred every three, four, or five weeks and were of very intense character. She had a slight internal strabismus of the left eye which she was entreated to have corrected. This was done under cocaine and she suffered no more from migraine.

Street Accidents in London.—It was stated recently in the British House of Commons that during 1903 1425 accidents resulting in personal injuries had been caused by covered vans in the streets of London, of which twenty-nine had been fatal.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held February 11, 1904.

DAVID BOVAIRD, JR., M.D., IN THE CHAIR.

Sporadic Cretinism.—Dr. LOUIS FISCHER presented several cases.

CASE I.—R. H., now over two years old, was first seen by him eighteen months ago. The child was breast-fed for seven months and later received equal parts of milk and water. Always constipated, and at times had severe tenesmus. She had course, sparse hair and a very rough skin. Tongue and lips were thick and the tongue protruded from the mouth. There was difficult breathing and snoring. The thorax was rachitic, there was a funnel-shaped depression, a kyphosis, and an umbilical hernia. The child could neither talk nor stand. There was no evidence of teething. The temperature was subnormal. The pulse was 100, small and feeble. The heart sounds were muffled. There was a hæmic murmur. There was a marked leucocytosis. The circulation was decidedly poor. The anterior fontanelle was widely open. Growth was decidedly stunted, the length of the body being only 55 c.mm. The naked weight when one and a half years old was 11 pounds and 13 ounces. At twenty-two months the first tooth appeared. The muscles of the body were limp and flabby. The child could not support its head and there was no tone to the spinal column. The patient was given fresh raw milk warmed; also steak juice, orange juice, potato flour, and the usual antiscorbutic remedies. Fresh albumin and vegetable proteids were well assimilated. Thyroid extract was given. Also Fowler's solution was administered in one-drop doses, increased to three drops, three times a day. During the six months' treatment the child had grown in length from 55 c.mm. to 69 c.mm. and the weight had greatly increased.

CASE II.—F. P. was first seen by him December 8, 1902, when the child was two years and two months old. She could neither walk nor talk. The tongue was thick and protruded constantly. The lips and skin of the face were thickened, coarse and rough. The nose was short and flat. The fontanelle was widely opened. The face was broad and eyes set widely apart. There was a marked depression on each side of the temporal bone and a marked frontal prominence. When twenty-two months old the child had nine teeth. The first tooth appeared one month after the thyroid treatment was begun, or when the child was sixteen months old. This treatment had been given at the Babies' Hospital. There was no evidence of rachitis. The body length was 50½ c.mm., or about 20 inches. Secretions of the body were torpid and constipation very obstinate. Thyroid gland could not be felt. The pulse was 90 and of a bounding character. The temperature was subnormal, and never higher than 98° F. in the evening. Respiration was 16 while quiet, and 24 while crying. One grain of thyroid extract was given three times a day and increased gradually to two and a half grains. There followed no cardiac disturbances. Ten drops of pure cod-liver oil were given three times a day. Cereals, milk, chicken soup, broths, acid fruits, etc., were given. The general hygienic surroundings were attended to. The body length at the end of the first month of treatment was 58½ c.mm., amounting to an increase of 3⅛ inches. The bowels became regular. The teeth have appeared at regular intervals. The child had begun to walk and talk. At the end of one year's treatment the body length was 85 c.mm., showing she had grown in one year 15½ inches.

CASE III.—R. N. was first seen by him June 28, 1902, when she was seventeen months old. The infant was nursed for about sixteen months, but did not seem to thrive since she was three months old. Severe constipation had always existed. She could neither stand, talk, nor walk. Backwardness in development was very apparent. The hair was coarse and straight. The extremities were short and growth much stunted. The lips were thick and the tongue large and protruding. Facial expression was senile. She had two lower incisors, but no other evidences of dentition. Equal parts of barley-water and milk were fed the child every few hours. One-half grain of desiccated powdered thyroids was ordered three times a day. This dose was gradually increased, and the child was now receiving three grains three times a day and without evidence of cardiac disturbance. Lemon and orange juices, raw albumin, vegetable soups, etc., were ordered. The condition of the child improved very much and the specific effect of the thyroid was very apparent.

Hernia of the Appendix.—Dr. HENRY L. K. SHAW of Albany presented specimen and drawings of this condition which occurred in a child, aged eleven months, who was an inmate of the Albany Orphan Asylum. The interest in the case was shown at autopsy. The abdominal cavity was free from fluid and the appendix was found extending into the inguinal canal; by traction on the appendix the testicle could be drawn up into the inguinal canal. The left testicle was very much thickened with fibrous tissue, as was its capsule. Section of the testicle showed a marked increase in the fibrous tissue. There was an orchitis as well as a periorchitis. He said that hernia of the appendix was a very uncommon condition, and was first described by Morgagni in 1750. In all since then probably as many as one hundred and thirty cases had been reported. This condition may be congenital or acquired. The majority of cases occurred in adults, and from fifteen to twenty in infants under twelve months of age. When the appendix passed through the inguinal canal into the scrotum adhesions took place between the appendix and the wall of the sac, peritoneum or testicle. Only two cases had been reported in which the adhesions occurred between the appendix and the testicle, and was supposed to be due to the persistence of the folds of peritoneum normally present, but undeveloped in the fœtus. Another theory was that there had been a fetal peritonitis, and this seemed to be the most plausible one. Quite frequently the appendix was situated extraperitoneally and situated close to the testicle before its descent into the scrotum; as a result of the orchitis and periorchitis, which were undoubtedly present, the two organs might have become attached and descended together. He referred to another theory of the persistence of the gubernaculum testis. He spoke of the fact that there had been reported eighteen cases of appendicitis occurring in infants and in six or one-third of these, there was found a hernia of the appendix.

A Clinical Study of Sixty-two Cases of Intestinal Infection by the Bacillus Dysenteriæ (Shiga).—Drs. L. E. LAFETRA and JOHN HOWLAND presented this paper. The report was entirely a clinical one. They said that it was now universally regarded that the Shiga bacillus was the etiological factor in dysentery occurring in adults. The studies had been made at the Rockefeller Institute of Medical Research. The cases under observation were seen at the Vanderbilt Clinic during July, August, and September, 1903. Several were visited and treated at their homes. All cases of even mild diarrhœa or intestinal indigestion were examined. Some patients were seen but once and undoubtedly some recovered quickly and so were not brought back to the clinic. There were sixty-two cases of infection by the dysenteric bacilli. From an analysis of the cases it was shown that there was an increased mortality with the increase in age, probably due to the fact that the majority of the infants were breast-fed. Of the sixty-two cases, sixteen were very mild, thirty-one moderately severe and fourteen severe. They made the following classification of the cases: (1) Mild cases, with temperatures under 100.5°, F. with the passages containing but little mucus. (2) Moderate cases, with temperatures over 100.5° F. and the passages containing mucus and some blood. (3) Severe cases, with marked constitutional symptoms with frequent mucous stools and often with

much blood. Thirty-four of the cases did not show a temperature over 100.5° F. The number of the stools in twenty-four hours varied greatly. In two cases the stools contained no mucus. Blood was present in seventeen of the cases. No clots of blood were noticed in any. Fourteen infants were breast-fed exclusively and none of these died. Forty-two of the cases were of the acid type and fifteen were infected with the true Shiga bacillus, while the rest were a mixed type. From an analysis of the sixty-two cases it seemed to them that the following conclusions were warranted: (1) There was a greater prevalence of dysentery in the so-called diarrhœas occurring in infants during the summer months than was generally supposed. (2) All types of diarrhœal diseases which were characterised by clinical symptoms were included; for example, both the mild and severe attacks of iliocolitis; even mild forms of intestinal indigestion were included. (3) As compared with the summer diarrhœas occurring in other years the small number was due to a cooler summer and to increased knowledge among the tenement population. (4) The striking number of breast-fed infants. (5) The serum treatment was not given in a sufficient number of cases to warrant any definite conclusion.

Dr. R. G. FREEMAN said there seemed to be a difference of opinion regarding the Shiga cases and the so-called acid type; it was not known whether they were due to the same organism or to varieties of the same. The cases that had come under his observation were of the acid type. In an epidemic quite near New York the real Shiga organism had been found.

Dr. HENRY L. K. SHAW of Albany said he had had some experience in Albany, and there was no doubt but that the cases seen by him were true cases of Shiga dysentery, occurring both in adults and in children. The Shiga bacillus had not been uniformly found in the stools of ordinary diarrhœas. Again in some true cases of dysentery the Shiga bacillus had not been found.

Dr. WILLIAM L. BANER said he had examined thirty cases in which the stools were watery or contained a little mucus, and he had never found the bacillus dysenteriæ in either the acid or alkaline type of the disease. In examining cases with mucus and blood in the stools there appeared so many varieties of bacillus dysenteriæ that he hardly could say whether acid or alkalide type of the bacillus, *i.e.* whether it was the true Shiga, or Flexner, or the one described by Duvall.

Dr. E. LIBMAN drew attention to certain defects in the work that was being done and which should be remedied. It seemed as if the bacillus was found when mucus was present and especially when there was also blood present. Therefore it looked as if they were dealing with an organism which might possibly be present normally in the upper part of the intestinal tract and which would multiply under certain conditions. As a rule when mucus was found in the discharge the bacillus was found. The upper part of the intestinal tract should be examined, a work that so far had not been done.

Diseases of the Accessory Sinuses of the Nose in Children.—Dr. LEWIS A. COFFIN presented this paper illustrating parts of it with lantern slides. An acute catarrhal or non-suppurative sinusitis was probably the most common and troublesome of these diseases. This affection occurring during the course of one of the infections, the sinuses of the nose, one or all, became infected and there resulted a suppurative sinusitis, the severity depending upon the character of the infection, the intranasal structure, the condition of the nasal mucus, and the physical equation of the patient. Those infectious diseases most likely to be accompanied or followed by sinusitis were the various exanthems, acute coryza and, above all, influenza. Trauma was an exciting cause. In the ordinary cases two symptoms were present, viz., profuse nasal discharge and pain. The discharge might be mucoid, mucopurulent, or purulent, and if confined to one side was most significant. The location of the pain in the head by no means located the disease, although this was a symptom of importance. In the more severe cases the pain was greater and might be felt in and about the eye, and there might be swelling of the lids and exophthalmia. This might occur with diseases of the anterior ethmoidal cells, frontal sinus and antrum, the point of greatest swelling, position of the eye or possibly a sinus opening, indicated which sinus was involved. Severe occipital pain, pain back of the eye, together with pus seen in the superior meatus, pointed to the severer type of sphenoidal disease. In the less severe cases every effort should be made to establish free drainage, and to this end sprays of a weak solution of cocaine and adrenalin should be used several times a day, together with frequent steaming of the parts. The internal administration of suprarenal extract had been of value in his hands. Intranasal probing and catheterizing in children was not practical, and one of the external openings and radical operations must be done. In adults various openings and routes to reach the various sinuses had been resorted to.

Dr. C. G. COAKLEY stated that Harper had performed autopsies on thirty children who had died of various infectious diseases and had found a suppurative involvement of the accessory sinuses in all.

Dr. W. L. STOWELL felt quite sure that many cases that were reported to be meningitis that recovered and that did not present any definite symptoms were not cases of meningitis at all but ethmoidal or other sinus disease.

Dr. EMIL MAYER said there were two definite conditions to be considered: (1) external injuries producing bone disease, terminating in fistula and an entrance into the accessory sinuses; (2) infections from such diseases as scarlet fever, diphtheria, etc.

CINCINNATI RESEARCH SOCIETY.

At a regular monthly meeting of the Research Society, held March 17, Dr. Wylie McLane Ayres demonstrated a variety of lesions of the optic retina by means of the new Thorner ophthalmoscope. Following this, Dr. J. Henry Schroeder and Dr. Henry W. Bettman presented a paper "Concerning the Acidimetry of the Gastric Juice" with demonstration. The paper was a practical consideration of the value of tropeolin OO, Toepfers dimethylamidoazobenzol, and Congo, as indicators for the quantitative determination (titration of free HCl in the chyme). After reviewing experimentally the typical behavior of these indicators with aqueous HCl solutions, their affinity for acetic and lactic acid was studied. All these indicators showed a greater affinity for lactic acid in even dilute solutions than for acetic acid.

The authors also gave the analyses of thirty specimens of gastric contents, as made with these indicators, showing the wide variations obtained with tropeolin OO and Toepfers reagent, due to the want of a good end-reaction with these indicators. They advocated the extraction of gastric contents with chloroform, when necessary, to remove organic acids. Drs. Schroeder and Bettmann, by the results as shown in their paper, refute entirely the claim of M. I. Knapp of New York, that he can estimate within the same specimen of chyme, by successive titration with tropeolin OO and Toepfer's indicator, the quantity of free HCl and organic acids respectively. They also showed that a test paper of Congo (for free HCl) must be allowed to dry before judging of the reaction; the weak reaction with organic acids usually disappears when the test paper is dried. Alizarin as an indicator was also discussed; the want of definite end-reaction pointed out. The authors stated that alizarin does not react with the phosphates (acid) of the gastric juice, as is usually believed.

To Remove the Odor of Iodoform and similar substances from glassware, etc., A. Haase advises washing with mustard.

Cincinnati Academy of Medicine.

At a regular meeting, on March 21, the following cases were reported: Dr. J. M. Withrow presented a "Tumor of the Uterus," removed at operation. The uterus was enlarged and contained a tumor the size of a small orange embedded in its upper anterior wall, hypertrophic uterine tissue being found both external and internal to it. It had a calcareous shell one-quarter inch in thickness which had to be opened by means of a saw, the center was soft and had not been examined microscopically as yet. The patient, Mrs. B., aged fifty years, was sent to Dr. Withrow by Dr. I. P. Gould of Bellevue, Ky. She had one child who died three years ago, at the age of twenty-seven years. She bore a dead child nineteen years ago. Eighteen years ago the patient thought she was pregnant, as menstruation had failed for three months, the abdomen enlarged rapidly for seven months, the tumor being loose and soft; repeated hemorrhage occurred. The patient received local electric treatment, and the tumor diminished greatly in size, hemorrhage ceased, and normal menstruation returned. The patient had three or four polypi removed from the uterus, the first in 1891. Thirteen years ago she miscarried at four months, later at eight months, and again at six months with twins. About six months ago she had hemorrhage from uterus, which had continued to the present time, a large amount of blood being lost at intervals. Then the tumor began to enlarge and pressure symptoms developed in the rectum and bladder, and legs felt tired and heavy. Physical examination showed the uterus to be movable with a large mass in its anterior upper part. The diagnosis of fibroid of the uterus was made and the organ was removed without difficulty on March 12. Dr. Withrow called attention to the failure of menstruation for three months eighteen years before, with abdominal enlargement and irregular hemorrhage, and gave it as his opinion that the tumor was the result of an ectopic gestation that had occurred in that part of the tube which lies within the uterine wall.

Dr. W. D. Haines presented an "Aneurysm of the Femoral Artery," which he had removed by operation. It was about as large as a hen's egg, and its anterior surface showed a rupture of all the arterial coats, while posteriorly the coats were intact, except for a few sclerotic patches. The patient, Mrs. M. Mc., age twenty-seven years; married, with nine healthy children, admitted alcoholism but denied syphilis. Late in February the patient lifted a wash tub and was taken with severe pain in the thigh, and soon noticed a pulsating tumor at the junction of the middle and lower thirds of the thigh. She found out for herself that pressure on the thigh above the tumor relieved her pain. After three weeks' rest in bed with the administration of potassium iodide, operation was done, the artery being tied above and below, and the sac dissected out. It lay in Hunter's canal between the profunda above and the anastomotica magna below. The operation was followed by delirium tremens, but at the time of the report the patient was doing well.

At a business meeting held the same evening, presided over by Dr. S. P. Kramer, the president, Dr. C. A. L. Reed, presented a letter addressed to the U. S. Senate, which he wished to have sent in the name of the academy. The letter urged the speedy passage of House Bill, 6295, entitled "A Bill for Preventing the Adulteration or Misbranding of Foods or Drugs, and for Regulating Traffic Therein, and for Other Purposes," as amended by the Senate Committee on Manufactures and now pending before the Senate. It was unanimously voted to send the letter to the Senate.

President Kramer then announced the following committees for the ensuing year: *Committee on Program*, Drs. Wm. Muhlberg, Samuel E. Allen, and Samuel Rothenberg. *On Hygiene*, Drs. Clark W. Davis, A. G. Drury, and Byron Stanton. *On Legislation*, Drs. Edwin Ricketts, Louis Schwab, a C. A. L. Reed. *The Committee on Progress* is composed of one man from eadh ward and from each township, and is constituted as follows: *Wards*, Drs. Stow Garlick, C. E. Caldwell, Samuel Iglauer, H. Kattenhorn, John Greine, W. E. Schenck, F. A. Kantz, Jr., Robt. Carothers, H. J. Whitacre, T. W. Hays, Edwin Khuon, G. S. Buttemiller, E. W. Mitchell, John Mitchell, Ambrose Johnston, John L. Cleveland, F. J. Erdhaus, Stephen R. Cone, J. H. Macready, B. F. Beebe, Geo. B. Twitchell, E. F. Landy, Louis Schwab, A. D. Stapleford. *Townships:* Drs. F. W. Lamb, R. C. Belt, Arthur Knight, John G. Williams, B. F. Lehman, C. W. Tangeman, W. C. Kendig. The following delegates were then elected for the Ohio State Society: Drs. S. P. Kramer, C. A. L. Reed, Louis Schwab, and Mark Brown; Drs. C. L. Bonifield, Geo. Fackler, D. I. Wolfstein, and Louis Stricker were elected as alternates.

Chicago Pediatric Society.

Dr. James W. Van Derslice read a paper before the March meeting on "Treatment of Bronchitis, Bronchopneumonia, and Pneumonia in Children." Among other things, he said that in many children there was a tendency toward catarrhal inflammations of the air passages. How to remove this tendency was a hard problem. No amount of cod-liver oil and tonics would overcome this predisposition without good hygiene. The temperature of rooms was kept too high. The temperature of living rooms should be 68° to 70°. Children should be accustomed to outdoor air. This should be begun in the summer and continued throughout the year every day except in case of a storm, when the child should be dressed for outdoors and taken into a room, with windows wide open, for twenty minutes to half an hour. A cold sponge bath of the chest and arms every morning was of value. The child's underclothing should be of wool, the lightest weight in summer, and only medium weight in winter. Chest protectors should be discountenanced. Care must be taken that the feet were kept warm and dry. The mistake in dressing the child was almost always on the side of too much rather than too little clothing. The sleeping room should always be supplied with fresh air, and the child should sleep in flannel night clothes. The sending of patients to a warmer climate during the winter season was necessary in a few cases, but he believed the majority of them did better in a dry, cold climate. He urged the use of inhalations of steam, which were best given in a tent by placing the medicament in a quantity of boiling water, as the use of lamps in a tent was objectionable. Three quarts of boiling water in an earthen vessel would produce steam for ten minutes, which was about the length of time these inhalations were usually given. They should be repeated every two to four hours. Simple lime-water inhalations were the best; later creosote, pine-needle oil, compound tincture of benzoin, terebene, turpentine, camphor, oil of eucalyptus, or eucalyptol might be used. Internal medication should be entirely symptomatic. The indications for treatment, in the main, were nutritional, stimulant, and hygienic.

Dr. S. V. Balderston read a paper on "Thoracic Difficulties of Childhood Exclusive of Cardiac; Differential Diagnosis." He urged a closer study of the physical signs in thoracic disease of children. Auscultation alone was not sufficient. Pile-driver percussion was not suited to the child's chest. In these conditions, dyspnœa, cough, cyanosis, and nervous manifestations might be called cardinal symptoms. One should study the conditions within the air passages and cavities which prevented free admission of air or caused irritation; also the conditions in the lungs and chest walls. Finally, the reflex and central conditions should be carefully studied. Croup was used as a comprehensive term to include a variety of conditions in which these was a tendency to spasm of the glottis. Enlarged tonsils and adenoids were usually present as an exciting cause. Cotarrhal spasm of the larynx might be confused with acute bronchopneumonia at the outset. History of afternoon hoarseness, amen-

ility to antispasmodics, and return of attack the follow- night indicated catarrhal spasm.

In mild cases of acute bronchitis the question was whether was merely a complication of another disease. At the st severe bronchitis could not be differentiated from umonia. Exaggerated, not bronchial, breathing was erved all over the chest. Any impairment of resonance suggestion of bronchial breathing excluded bronchitis. capillary bronchitis no attempt was made to differenti- the condition from bronchopneumonia.

Bronchopneumonia signified a low resisting power. It ented the symptoms of a mixed infection. At the on- there were marked prostration and cyanosis and a iable temperature, either very high or very low. There re indefinite areas of consolidation and bronchial thing, marked dyspnœa, and great mortality. In ar pneumonia the physical signs were all-important; re was the most difficulty in central consolidation. physician should watch for bronchial fremitus. The racteristic signs were defined area of dulness and chial breathing. He presented the following table the differential signs in *bronchopneumonia and lobar umonia* in childhood:

Bronchopneumonia	*Lobar Pneumonia*
Usually secondary to an acute disease.	1. Frequently primary.
Usually in children under two years.	2. Common after second year.
Convulsions and vomiting common at onset.	3. Not so common.
Cyanosis at onset.	4. Not usual at this stage.
Both lungs usually affected.	5. Usually one lung only.
No well-marked area of dulness, and bronchial breathing.	6. Area well defined.
Irregular temperature.	7. Temperature steadily high.
Rarely terminates by crisis.	8. Usually terminates by crisis.
Recovery rare.	9. Percentage of recovery high.

In chronic conditions the question was as to whether or there was infection by the tubercle bacillus. In es of chronic cough and chronic pneumonia following ertussis and measles, enlarged tonsils and adenoids ght serve to keep up the cough. Enlargement of the nchial glands irritated the recurrent laryngeal. This largement might be tuberculous or not. In children berculous infection of the lungs probably started from e center through infection from these glands; hence there s rarely infection of the extremes of the lung. Cavern- s breathing and cracked-pot sound did not indicate ity, but consolidation about a bronchus. The family tory should be carefully investigated, likewise the su- ndings, and an examination should be made for foci in her parts of the body.

OLLEGE OF PHYSICIANS OF PHILADELPHIA, SECTION ON GENERAL MEDICINE.

At a stated meeting, held March 14, Dr. Clifford B. er exhibited "A Case of Hernial Protrusion of the ung." The patient was an elderly woman, with per- tent cough, from the violence of which a pouch, ap- rently of lung structure, was projected above the ft clavicle, receding with inspiration. The mass was ft, vesicular, and tympanitic. The jugular veins also come filled with the violent expiration of cough. While the condition may not be infrequent, it has received tle attention in the literature, and but a small number f cases are on record. Dr. W. B. Stanton exhibited "A Patient with Pulsating Empyema." The case ccurred in a young man, employed as a car conductor, n whom the signs of left-sided pneumothorax were iscovered in the absence of a history of sudden onset, ith pain and other characteristic symptoms. Tubercle- acilli were present in the sputum. Under treatment in he open air and with over-feeding marked improvement nsued, while the signs of pneumothorax disappeared nd were replaced by those of pleural effusion. A moderate amount of slightly purulent fluid was removed by aspiration. At a later period signs were found of the presence of a considerable amount of fluid in the chest on the left side, the heart being displaced markedly to the right, and pulsation of the intercostal spaces on the left being distinctly visible. The pulsation became less pronounced after the removal of a moderate amount of fluid. Dr. Stanton referred to several other cases in which pneumothorax had developed insidiously in tuberculous subjects without the symptoms considered characteristic. Dr. Herman B. Allyn read a paper entitled "Remarks on a Severe Case of Appendicitis Ending in Recovery without Operation." The patient was an elderly man, who on two occasions was seized with abdominal pain, nausea and vomiting, with constipation, attributed to oysters that had been previously eaten. There was some rigidity of the abdominal wall, and in a day or two a mass was clearly distinguishable in the right iliac fossa. A surgeon called in consultation was unwilling to operate on account of the poor condition of the patient, expressing the opinion that the man's chances of recovery were better without surgical intervention. A second clinician, who saw the case in consultation, concurred with the first in the suggestion of operation, but the surgeon maintained his original decision. The patient eventually recovered. It was pointed out that surgeons, from having been considered the more radical, are now apparently the more conservative, while clinicians have become the more radical with respect to operation for the relief of appendicitis. In the discussion it was stated that the recovery under medicinal treatment of a patient suffering from appendicitis means the death of several others, in whom the hope of recovery without surgical treatment will give rise to disastrous delay. Observation has shown that the results are better at the hands of surgeons who operate on all cases of appendicitis at the earliest possible moment, that is as soon as the diagnosis is made, than at the hands of those who are unwilling to operate or defer operation for more propitious conditions. Drs. J. H. Musser, James W. Wister, and Norman B. Gwyn reported "A Case of Acute Hemorrhagic Leukæmia." The patient was a large, vigorous man, fifty-three years old, in whose urine albumin and tube casts had for some time been present, and who without obvious cause began to feel ill. A number of hemorrhagic extravasations appeared about the forehead where pressure was made by the hatband. The temperature rose, and the parotid, submaxillary and cervical glands became enlarged. The structures of the throat were red and swollen. Examination of the blood disclosed a reduction of the hæmoglobin to about 60 per cent., with a corresponding reduction in the number of red corpuscles, but with an increase in the number of colorless corpuscles to nearly 300,000, lymphocytes preponderating to the proportion of about 98 per cent. The condition of the patient grew progressively worse, and death took place on the forty-third day of the final illness. Dr. Robert N. Willson, Jr., read a paper entitled "The Diagnosis of Incipient Phthisis, with Special Reference to the Physical Signs and the Frequency of Bacilli in the Sputum." He dwelt upon the importance of a careful physical exploration of the chest in cases with obscure symptomatology, particularly with cough of unexplained origin, wasting, languor, malaise, chilliness, and sweating, and upon the necessity of prolonged and repeated examination of the sputum in cases attended with expectoration. He cited cases with slight symptoms and physical signs in which tubercle bacilli could be demonstrated in the sputum only on most careful and repeated examination, and other cases in which, despite marked physical signs, characteristic symptoms were wanting. Dr. Henry M. Fisher exhibited "A Large Urinary Calculus Passed by the Urethra." The pear-shaped concretion appeared to be composed of uric acid and weighed 17 grains. It was voided, with some pain by a woman,

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

IMMUNE SERA, HÆMOLYSINS, CYTOTOXINS, AND PRECIPITINS. By Prof. A. WASSERMANN, M.D. Authorized Translation by Charles Bolduan, M.D. First edition. 12mo, 76 pages, illustrated, cloth. John Wiley & Sons. New York. Price, $1.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending April 2, 1904:

	Cases.	Deaths.
Measles	1265	28
Diphtheria and croup	343	39
Scarlet fever	393	30
Smallpox	...	
Varicella	56	...
Tuberculosis	289	185
Typhoid fever	19	12
Cerebrospinal meningitis	...	31

An Unusual Accident.—An accident somewhat out of the ordinary occurred in Chicago's suburbs not long ago. A man crossing the tracks was struck by the New York limited while it was running at full speed. The thermometer was 10 below zero at the time. Instead of being killed outright, he was thrown in the air by the cowcatcher, fell back on the top of the latter, and saved himself by clinging to some rods. In this position, with a broken leg and two broken ribs, he remained for four miles, until the train was stopped. Several bystanders saw the man struck by the train, and after it had passed searched the vicinity with lanterns for the body. Not finding even a shred of clothing, it occurred to someone that he might be on the engine. The first stop of the limited is seventy-five miles out, but by telegraphing ahead it was finally stopped, the man extricated and taken to a hospital, where he was reported as resting well at last accounts.—*The Railway Surgeon.*

Drainage of the Pericardium.—Mintz has elaborated the following technique, which is a modification of a method proposed by Larrey in the early years of the last century. He has used it once on the living subject with success, in order to drain a suppurative pericarditis. The upper portion of the body is slightly elevated and the operator stands at the right. An oblique incision seven c.m. in length is made along the free border of the left seventh costal cartilage, beginning at the sternochondral angle. The muscles are separated from the lower surface of the costal cartilage, and it is divided transversely at the two ends of the incision. The flap so formed is then turned upward, the insertion of the diaphragm being pushed back. The transparent pleura and less delicate pericardium are readily identified by pushing down the diaphragm slightly with the finger. The excellence of the drainage to be attained in this way is shown by the fact that even in the normal cadaver pericardial fluid usually escapes.—*Zentralblatt für Chirurgie*, No. 3, 1904.

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended April 2, 1904:

TUBERCULOSIS HOSPITALS OF THE EW YORK STATE HOSPITALS FOR THE ISANE.

By FREDERICK PETERSON, M.D.,
RESIDENT OF THE NEW YORK STATE COMMISSION IN LUNACY
AND
G. L. HEINS,
STATE ARCHITECT.

RE are in the neighborhood of 25,000 insane in pitals in the State of New York. An estimate he number of cases of tuberculosis in the State spitals has been made, and while the population

UBERCULOSIS PAVILION, "EDGEWOOD," AT THE BINGHAMTON STATE HOSPITAL, SHOWING THE STAGE OF CONSTRUCTION, DECEMBER 11, 1903.

higher in the hospitals situated in the cities as mpared with those situated in the country, the erage of tuberculous patients among the insane opulation is about two per cent. This ratio is most the same as that of the London County sylums, where Dr. Mott has recently made an vestigation of the matter. In a population of ver 14,000 insane he estimates the ratio of cases f tuberculosis to be 1.72 per cent.

The Lunacy Commission of New York State has or several years favored the segregation, as far as ossible, of these patients from the others. In many of the fourteen State Hospitals under its risdiction special wards have for some years been et aside for tuberculosis cases, and where possible olariums have been added to such wards.

Dr. A. E. Macdonald, Superintendent of the Manhattan State Hospital, East, on Ward's Island, suggested the use of tents for patients with tuberculosis, and his suggestion was promptly acted upon by the Lunacy Commission. At first tried during the warm months only, Dr. Macdonald has found it expedient and satisfactory to keep the tents occupied all winter, having the tents warmed by stoves. This plan he has successfully carried out for three winters.

The Lunacy Commission, after ascertaining that we have in the State Hospitals upward of 500 cases of tuberculosis and a constantly growing insane population, determined to establish properly constructed tuberculosis hospitals in the State, in connection with certain of the hospitals so situated as to offer the best climatic advantages. At firs it was intended to build six hospitals, each for fifty cases of tuberculosis; but for economical reasons, centralization of heating, administration, supplying food, etc., the plans were subsequently modified. We have now three hospitals with one hundred beds each, to be established in different parts of the State, anticipating a later provision for two or three hundred tuberculous patients at the proposed new colony for the insane in the northeastern portion of the State.

In dealing with insanity as well as tuberculosis, our problem in construction has necessarily differed somewhat from the plans evolved for tuberculosis sanatoria in general. In the matter of constant watching of patients, for instance, the need of dormitories with a few single rooms only in place of many single rooms is a pertinent feature.

G. L. HEINS.
STATE ARCHITECT.

bligations to Dr. Trudeau for courteously examining the plans and offering suggestions.

It will be observed that there is a central building with two wings joined by one-story corridors. The buildings are two stories high. The central building has a kitchen, pantry, and dining room on the first floor and bed room for employees above. The second stories of the wings are for able-bodied patients, the first floors for the bed-ridden.

Each ward has space for sixteen or seventeen beds, and there are six single rooms connected with each ward. The water section, with baths, toilet, etc. is effectively separated from the main body of the structure. Sitting-room space has been made very small, so that patients shall remain outdoors as much as possible. The hospital has a southerly exposure for both wings. Taking the first floor (for bed-ridden patients) as an example, there are practically two verandas—one uncovered to the south, to which the beds may be wheeled and the patients given sun baths in suitable weather, with

bed awnings to shade the face and eyes. There is one on the north which is almost wholly glass, and which serves both as a corridor and veranda. To this northern veranda the beds can be wheeled in inclement weather or for the sake of coolness in the heat of summer. The dormitory of the ward is practically surrounded with glass—the whole front is glass and there is glass some distance along each side. The wall between the corridor and veranda is lined with transoms opening into the corridor its whole length. Thus, whatever may be the weather or prevailing wind, two or three sides of the dormitory may be always open if desired. All of the windows reach to the ceilings, and all are provided with transoms flush with the ceilings, so that there can be no stagnant air in the high strata of the room. These transoms are hinged at the top and open outwardly, where they open directly out of doors, in order to protect the rooms from rain. The ceilings are made rather low, as is usually advised in these hospitals, 10 feet, so they may readily be cleaned. Every effort to avoid angles and corners anywhere in the rooms is to be made. The doors are to be without panels, the angles at the junction of floors, walls, ceilings, etc., well rounded. The floors will be covered with linoleum; enamel paint will be used up several feet of the walls. The heating system is an unusual feature, and has, as far as we know, not been employed in other hospitals of this kind. It is used in the new maternity hospital built and endowed by Mr. J. Pierpont Morgan in New York City. The steam pipes are laid along on both sides of the wall dividing the dormitory from the corridor, and on available wall space in single rooms. The pipes are then completely covered with sheet iron and coated with white enamel paint. Thus no dust or expectoration can reach any part of the pipes, and the whole apparatus can be kept as clean as the floors or walls. Enclosing them thus demands, of course, a much larger supply of steam pipes and a greater radiating surface, especially in wards into which so much glass construction enters; but as tuberculosis wards should properly be kept at a temperature only a moderate degree higher than the outside air, it is expected that the plan adopted will prove satisfactory.

For each ward a drying room and a clothes closet is provided at the back of the corridor, where patients coming in from outdoors may divest themselves of heavy or wet clothing, and hang it up to dry.

Whenever possible, the southerly slope of a hill with woodland protection is selected as a site. The first of these hospitals is now nearing completion at Binghamton. The site selected is on the south side of a high hill with a forest behind. It is ideal in every respect. The slope is such that exit may be had from the second story to the hill above without going down stairs. It is so accessible that steam can be furnished from the central heating plant of the institution and easy connections with the sewer, water, and lighting systems made.

The other two tuberculosis hospitals are to be constructed on the grounds of the State Hospitals at Middletown and Ogdensburg.

4 West Fiftieth Street.

Carbon Bisulphide in Sciatica.—This substance applied to the skin over the painful areas produces the sensation of intense cold followed by a feeling of intense heat. The pain only lasts a few moments. It has also been successfully employed in abscess, neuralgia, acute inflammatory conditions, and acute rheumatism.—G. G. Corbet, in *The Maritime Medical News*.

THE DEFICIENT UREA-EXCRETION IN GOUT AND LITHÆMIA.

By RICHARD K. MACALESTER, M.D.,
GLENWOOD SPRINGS, COL.

Some four years ago, while engaged in determining the relation of uric acid to urea in gouty patients, I gained conviction that this was a very variable proportion, from which little practical diagnostic or therapeutic knowledge could be obtained. On the other hand, I was impressed by the fact that these two components were constantly present in diminished quantity in the urine of the gouty, and in a symposium paper the following observation was reported:[1] "In a goodly number of urinary analyses of gouty patients made by me during the past three years, the above enumerated findings have sometimes been obtained, but by no means in the majority of cases, even in which gout has become eminently chronic, does the urine reveal the coexistence of kidney disease. But common to all cases of gout, as well as lithæmia, its next-door neighbor, my quantitative uranalyses show, without exception, a marked diminution in the daily amount of urea excreted, quite independent of the slightest evidence, either chemical or microscopical, of a coexisting renal lesion. I report this observation here, being unable to find in the literature, notwithstanding an extended search, any record of this deficient urea excretion, except in conjunction with Bright's disease and general marasmic conditions, and I hope to be able to collect sufficient material to present more conclusive results in a future communication."

In addition to the foregoing may be mentioned such references as: in chronic or cachetic gout, the urea appearing in normal quantity, or very nearly so, unless there is renal trouble, and the amount excreted being in relation to the diet and to the extent of metabolic force available in the liver (Dyce Duckworth). Before an acute attack of gout (Garrod), and an uric-acid headache (Haig) the amount of urea being diminished. But in these and other reports no allusion is made to a permanent deficient urea-excretion as characteristic of the gouty condition.

Since the publication of my paper my views have been amply corroborated by further investigation, and in order to demonstrate my standpoint I shall, as examples, enumerate in the following twenty uranalyses of gouty and lithæmic patients with a brief synopsis of the history and principal positive findings in each case, taken from my case book at random. These are mostly examples of lithæmia and so-called incomplete or irregular gout (that is, gout manifesting itself anywhere but in a joint), in some of which, however, typical acute paroxysms have previously manifested themselves; but cases presenting any clinical evidence of nephritis, and marasmic conditions, have been purposely excluded.

The irregular forms of gout and lithæmia seem to be our most common American types of the disorder; nevertheless, I have observed in this country a few cases of regular, sthenic gout, worthy of Sydenham's classical descriptions. In England, too, incomplete gout is more prevalent at the present day, and even nearly forty years ago it was remarked that typical acute cases were less frequently met with than in earlier days (Burrows), many of the manifestations of gout being obviously modified by inheritance and mode of living. Hence it is not surprising that in the United States, under totally different surroundings, the disease should assume divers new phases and types, and it is

conviction that such forms and lithæmia—in which term much confusion exists—are of common origin, and nothing less than modified gout. Duckworth's dictum aptly puts it: "No lithæmia, no gout." My belief, that irregular gout and lithæmia are modifications of one and the same disease, is not only based upon an extended study, but also upon the urology of these disorders, the results of my uranalyses (Table II) showing uniform relations.

For the purpose of comparison with Table II, the results of the uranalysis of twenty cases of various other chronic disorders are collated in Table I.

The average daily urea-excretion in a healthy, middle-aged subject of medium weight, and on a liberal mixed diet, is given by the majority of authors as about 30 gms. The daily urea output, estimated by me, in twenty healthy persons (ten men and ten women, living approximately under the same conditions, and of ages corresponding closely with those of my patients) was 29.65 gms., the averages of their uranalysis being:

TOTAL URINE MEAS., C.C	SPEC. GRAV.	TOTAL SOLIDS.	UREA PER CENT.	TOTAL UREA.	TOTAL URIC ACID.
1362.5	1.204	68.31	2.445	29.65	.678

As aforesaid, mention is frequently made in the literature of a deficient urea-excretion in gout, in conjunction with impaired renal function, but here the kidneys were always effected, and the condition was attributed thereto. Appended are my averages in ten cases of chronic Bright's disease, without gouty symptoms, in which, the daily urea-excretion being decidedly below the normal, conforms with this conclusion:

TOTAL URINE C.C.	SPEC. GRAV.	TOTAL SOLIDS.	UREA, PER CENT.	TOTAL UREA.	TOTAL URIC ACID.
1760	1.015	56.595	1.357	21.936	.421

All the enumerated analyses were made by means of *clinical* methods, with much care and attention given to details, and in case of doubt, the estimation was always repeated.

The *solids* were obtained from the specific gravity through Haeser's coefficient.

The percentage of *urea* was determined by the *improved* Doremus' ureometer and the sodium-hypobromite solution freshly prepared for each estimation—a most essential procedure, this mixture deteriorating in a remarkably short time. In the results of the estimations, allowance was made for the altitude.

The *uric acid* was estimated by Heintz's method. Although precision is not claimed for this simple method, the inaccuracy is trivial if one observes certain precautions, such as: Using *fresh* stronger HCl, *cooling* the urine, and allowing it to stand for forty-eight hours, washing the precipitate with cold, *acidulated* water, then drying thoroughly, and adding to the amount of uric acid obtained by weight in every 200 c.cm. of urine, .0096 gm. for the quantity remaining in solution.

The patients and other subjects were instructed to adhere to a certain régime several days before, and while collecting the urine, to take exercise, drink water freely, and a liberal, mixed diet was prescribed. This last direction is a *sine quâ non*, it having been repeatedly proved that the output of nitrogenous matter is, to a great extent, dependent on the food. Thus, A. E. Taylor,[2] in a series of personal experiments, demonstrated that the average daily urea-excretion was: 59.021 gms. on a heavily proteid diet, 40.750 on a mixed normal, 23.430 on a purely vegetable, and 7.738 on a nitrogen free diet. Lehmann[3] found: On animal diet, 819 grs. of urea *per diem*, and on non-nitrogenized food, 237 grs.

On inquiry, I find that practitioners are usually content with ascertaining the percentage of urea of their patients, *i.e.* with having a sample of urine examined, without knowledge of the total for twenty-four hours. For obvious reasons—as will be seen by comparing, for instance, cases VIII and XVII, Table II—this is a useless practice, from which no deductions relative to the total urea output can be drawn.

To obtain the total urine for twenty-four hours is not always an easy task. The subjects are given, graduated two-quart jars (containing a little camphor or chloral to avoid decomposition), with explicit instructions, among others, not to fail to use them each time an inclination is felt to urinate and especially before defecation.

Case I.—Gout. Well-developed, strong man, æt. forty-nine years, weight 154½ pounds. Heredity. (In this and the following cases heredity signifies a gouty or rheumatic history in the patient's near progenitors.) Had several attacks of acute gout in feet previously, but for ten years past the disease has remained more chronic. Putty-like and harder deposits in finger-joints, elbows, feet, and knees. Widespread psoriasis vulgaris for many years.

Case II.—Gout. Man, æt. fifty-one years, weight 190 pounds. Heredity. Robust and active, though frequently feeling some mental fatigue and headache. Habits excellent. Nodular deposits in distal finger joints of both hands, and on the dorsum of left foot, which become tender and painful at times.

Case III.—Gout. Woman, æt. fifty-one years, weight 208 pounds. Sedentary habits, and always fond of high living. Deposits in, and thickening of, the epiphyses of the digits; chalky deposits (tophi) in ear lobes. Eczema squamosum of face and feet. Growing stout of late, but the gout and eczema developed over ten years previously.

Case IV.—Gout. Woman, æt. sixty-two years, weight 115½ pounds. Always delicate, though active. Had two attacks of acute rheumatism and asthma for thirty-five years. Typical gouty deposits in finger-joints and great toes.

Case V.—Gout. Woman, æt. forty-seven years, weight 138 pounds. Subject to attacks of asthma and muscular and arthritic pains for many years. Hard and soft deposits in, and thickening of, the articular cartilages of fingers and toes, and some swellings of the tendons. Periodical exacerbations, but almost constant pain.

Case VI.—Gout. Man, æt. thirty-three years, weight 121 pounds. Heredity. Always subject to urticaria, and since 1895 to attacks of pain and swelling of various tendons and joints, these last-named remaining enlarged since 1899, but with little or no pain, except on violent motion. Hard and chalky deposits in joints, tendons, and bursæ of hands, feet, and knees.

Case VII.—Gout. Woman, æt. fifty-seven years, weight 112 pounds. Gastric and rheumatic troubles preceded the onset of gout for about eight years. Now, soreness and numbness in hands and feet and stiffness in knees; thickening of epiphyseal cartilages, harder and softer deposits in finger- and great-toe joints, and periarticular swelling of

knees. Intense itching (pruritus) of skin, especially at night.

CASE VIII.—Gout. Man, æt. fifty years, weight 167 pounds. Heredity. Always had asthma. Some alcoholism, and smokes inordinately. Had first attack of gout in left foot, then in right; feet have been tender and stiff since. Tendons of feet swollen and nodular, small deposits in joints of great toes, which are puffed and extremely painful. Patient had an acute exacerbation of typical gout while taking the cure here.

CASE IX.—Gout. Man, æt. forty-four years, weight 182 pounds. Heredity duration, fourteen years. Had previously a number of acute attacks in feet, knees, and more recently in hands. Being a brewer, indulged in alcoholic beverages inordinately. Was always a hearty eater. Very robust and powerful. Status præsens: Eczema seborrhoicum, head and forehead; uratictophi; r. ear-lobe; soft, fluctuating, and harder deposits in finger-joints, bursæ, and tendons. Right elbow swollen, painful, and knotty. Crepitation and loud crackling knee-joints. Nodular deposits in various muscles and tendons.

CASE X.—Gout (rheumatic gout: Dr. Good, Paris). Woman, æt. forty-six years, weight 146 pounds. Heredity. Always robust and active, but of "catarrhal constitution," and subject to attacks of headache and relaxation. Drank wine habitually till recently. Periarticular thickening of, and deposits in, finger-joints, growing in size and consistency, and causing at times much pain and stiffness. Finger- and toe-nails atrophic and brittle, with white spots. In 1902—one year later—the total urea was estimated by me as below 17 gms., and by Dr. Gardiner of Colorado Springs as about 180 grs. per diem, in 1903.

CASE XI.—Gout. Woman, æt. forty-two years, weight 118 pounds. At age of four years inflammatory rheumatism. Since youth afflicted with hay-fever and asthma. Always rather delicate, but active. Often had rheumatic pains in muscles and joints. Gums spongy and receding. Heberden's nodes and soft deposits in extensor-tendons of fingers.

CASE XII.—Lithæmia. Man, æt. forty-eight years, weight 191 pounds. Heredity. Intense perspiration and eczema in hands and feet, for over five years. Habitual wine drinker. For many years pains and soreness in various muscles and joints, and distressing burning sensation in soles of feet.

CASE XIII.—Gout. Woman, æt. sixty years, weight 134 pounds. Heredity. Onset fifteen years ago, but symptoms increasing in severity steadily the last two years. Hard nodular enlargements, and exostoses of finger- and great-toe joints, with deformity of these extremities.

CASE XIV.—Lithæmia. Man, æt. thirty-three years, weight 153 pounds. For three years under considerable mental strain. Loss of ambition and energy, occasionally sick headaches, or neuralgic attacks starting around the eyes, paræsthesiæ (creeping sensations) in extremities, and frequently muscular pains. Not particularly depressed, but mind is apt to dwell on queer and repulsive things. "Abscessions and paræsthesiæ, at times bordering on melancholia" (Dr. F. W. Langdon). Some alcoholism and tobacco.

CASE XV.—Gout. Woman, æt. fifty-nine years, weight 197 pounds. Heredity. Fond of high living and growing stout of late. For seven years periodical attacks of pain and stiffness in knees, repeated paroxysms of pain in the soles, and gnawing in joints of the feet. Nodular swellings and tenderness in extensors of left thumb, and doughy deposits at the base of both thumbs. Hallux valgi.

CASE XVI.—Gout. Woman, æt. sixty-seven years, weight 155 pounds. Rheumatic (?) for many years. Scaly eczema over feet and legs, with intense itching. Severe pains in legs and feet, concentrating in the joints. Ankles tender. Soft swellings and deposits in tendons of both extremities.

CASE XVII.—Gout. Man, æt. sixty-seven years, weight 148½ pounds. Heredity. Robust and active; habits excellent. For twelve years occasional attacks of pain and swelling of the feet, especially the tarso-phalangeal joints of the great toes, lately involving the knees and fingers. Joints of fingers and great toes nodular and deformed, large exostoses on inner surface of left calcaneus, and tendo achillæ nodular.

CASE XVIII.—Lithæmia. Woman, æt. fifty-two years, weight 130 pounds. Heredity. Always subject to bilious attacks, and intolerant to gouty foods and beverages. Marked physical and nervous exhaustion. Five years ago sprained right foot, since when it has been entirely disabled, inflamed and very sensitive, with frequent exacerbations of inflammation, swelling and painful paræsthesiæ so that patient is permanently invalided.

CASE XIX.—Lithæmia.—Man, æt. twenty-three years, weight 138½ pounds. Indulged in much exercise (bicycling) formerly; for last two years over-ambitious doing confining, clerical work, and under considerable mental strain. Suffers from headaches, exhaustion, eye-blurring, uneasiness, worry, and fear of breaking down altogether. Has vague muscular pains in back of neck, legs and lumbago region, and feels as if he were shaking all over.

CASE XX.—Lithæmia. Woman, æt. thirty-seven years, weight 128 pounds. Heredity. Onset three years ago, following typhoid fever. Aversion to her former surroundings, anæmia, physical and mental depression, bilious attacks, digestion being fair only when adhering to a strict diet, oppression in head, painful sensations and tingling in extremities, and as if the inside of her body were not strong enough to support her. An eminent New York neurologist pronounced this a case of mild melancholia, in which Dr. F. W. Langdon of Cincinnati, who kindly referred the patient to me, could not concur, being of the opinion that her condition was dependent on defective elimination. After a two months' course of treatment at Glenwood Springs, the morbid mental symptoms abated to a great extent, and nutrition and strength improved remarkably. Now well for nearly two years. Mention of arteriosclerosis was omitted in the enumerated cases, it having been found almost invariably present in some degree.

By comparing the results of the foregoing analyses, it will be seen that the urine of the gouty is approximately normal in quantity, of rather low specific gravity, and notably poor in solids.

The average *total urea* shows a remarkable diminution in the amount excreted, it being not only below the normal in health, but considerably below the averages in all the other tabulated disorders. And even in the large majority of the enumerated individual cases, this urea-deficiency in the gouty is apparent. Hence, the relative averages of the tables demonstrate the fact that the total urea output in gout is considerably below that in chronic nephritis, about two-thirds of the amount obtained in the enumerated miscellaneous, chronic dis-

ers, and only about three-fifths of the quantity reted in health.

The average *percentage* of urea in gout is also ow that in health, and in other diseases, with exception of chronic nephritis, in which trouble, ng to the usual concomitant polyuria, the urea-centage is lower.

The *uric-acid* excretion in gout is far below that ther conditions, and in health. It not being the

ase, is much exaggerated (Billings,[4] Woods-Hutchinson[5]). And, contrary to others, my observations monstrate the uric-acid excretion to be, in a rtain degree, commensurate with that of urea, ot only in gout, but also in other disorders, and health. Thus, it is distinctly stated that there ists no definite relation between the discharge f urea and uric acid, either in cases of acute or hronic gout, the excreting functions of the kid-eys for these two substances being separate and independent of each other (Garrod, Haig). In health the ratio is given as 1:33, the excretion being found to be increased or diminished together.

Remarks: From a physiological point of view, urea is the most important solid constituent of the urine, it being the chief product of the metamorphosis of the albuminous tissues, and furnishes the form under which nearly all the N finds its way out of the body (Wm. Roberts[6]). In short, the amount of the daily urea excretions is, in a measure, an index of the changes in nitrogenous tissue metabolism as well as of the energy with which the splitting-up process of albuminous food elements in the economy takes place.

In view of the one moiety of urea, and the variations in its excretions, depending on the quality and quantity of the food, I have, as aforesaid, endeavored to preclude, as far as possible, any discrepancy in the amount of nitrogenous material consumed, by regulating the dietary of my cases, *i.e.* by prescribing the same diet for all before and during experimentation. And still the gouty cases show a remarkably low urea excretion.

What is the cause of this urea deficiency? Is it dependent, primarily, on hepatic or renal disturbance? I incline to the former view. It is now generally conceded that the liver constitutes the chief seat of urea formations, as was originally claimed by Meissner, and afterward confirmed by Brouardel, Schroeder, and Minkowski (Purdy[7]), and others. The deficient urea output, found in the tabulated cases, would seem to indicate perverted metabolism due to functional hepatic derangement, there being besides many other clinical symptoms and complications that point to the liver as being at fault, and lend color to the old Murchison hepatic theory of gout. On the other hand, we have in the cases under consideration, no clinical evidence of kidney trouble in support of the renal theory.

From a diagnostic and prognostic standpoint the presence of this urea deficiency is very important, and has frequently proved a valuable adjunct in my hands. To establish a correct diagnosis between gout and chronic rheumatic conditions, and between lithæmia and certain nervous affections due to other causes, is in some cases extremely difficult, if not impossible, at first sight. In chronic rheumatic affections—a collective term used for convenience sake, embracing chronic rheumatism, rheumatoid arthritis, osteoarthritis, etc.—the results of the urinary analyses do not appear to deviate materially from the normal.

In a number of cases, I have hesitated in pronouncing for gout or rheumtaism, and deferred making a definite diagnosis until after having obtained the uranalyses. The results thereof have cleared up the situation, and conclusions based thereon have, subsequently, been invariably substantiated by further observation, and "ex juvantibus." In my experience, gout has proved far more amenable to treatment than chronic rheumatism, and I still maintain as optimistic views relative to the beneficial results of balneotherapy in gout as expressed in a previous communication.[8] Sir Dyce Duckworth's Treatise on Gout (London, 1890) contains a complete list of the literature up to the date of publication, from which quotations not asterisked in the foregoing are taken. In concluding, I desire to express my appreciation of this excellent work, which has been a valuable aid to me in the study of the subject.

SUMMARY.

1. Persistent deficient urea-excretion is always present in, and characteristic of, chronic gouty conditions.

2. The total urea output in gout is considerably lower than that found in chronic Bright's disease, about two-thirds of the amount in other miscellaneous chronic disorders, and only about three-fifths of the quantity, excreted in health.

3. Deficient urea-excretion is an important factor in the differential diagnosis between gouty and chronic rheumatic troubles, and between lithæmia and certain nervous conditions dependent on other causes.

4. It is not present in chronic rheumatic conditions.

5. It points to perverted hepatic metabolism, and lends color to the Murchison theory of gout, there being in the cases discussed no clinical evidence of kidney trouble in support of the renal theory.

6. A diminished uric-acid excretion is to a certain degree commensurate with that of urea.

7. Gout, goutiness and lithæmia are of the same origin, and but modifications of the same disorder.

8. Chronic gouty conditions are in general more amenable to treatment, especially to balneotherapy, than chronic rheumatic affections.

OPERATION FOR CONGENITAL SADDLE-NOSE BY INTRODUCTION OF A CELLULOID PLATE.

By JOSEPH WIENER, Jr., A.B., M.D.,
NEW YORK.
ADJUNCT ATTENDING SURGEON, MOUNT SINAI HOSPITAL.

Much has been written during the past few years about paraffine injections for the cure of the deformity known as saddle-nose. While the results on the

Fig. 1.

whole have been satisfactory, the procedure is not free from danger. Numerous cases of embolism have been reported, occasionally followed by serious lesions. The introduction of a celluloid plate is a simple, safe, and efficacious operation, free from the dangers attending the subcutaneous injection paraffine. Almost three years have elapsed sin the celluloid plate was introduced in the case n rated below, so that the patient can be looked up as permanently cured.

Mr. X., thirty-five years old, was referred to me his family physician in April, 1901. The man sta

Fig. 2.

that he had been born with the deformity with wh he presented himself. In place of the bridge of nose there was a marked depression between nasal bones above and the cartilage at the tip of nose. The resulting deformity was a combinat of the so-called pug-nose and saddle-nose. (Fig. 1.) A sister of the man had been born wit hare-lip. The remaining brothers and sisters had no deformity of any kind. There was no tory of congenital or acquired lues. The wife of patient had always been in good health, and given birth to several healthy children; she had no miscarriages.

On April 29, 1901, under chloroform anæsthe I made an incision one-quarter of an inch long, in median line on the under surface of the n Through this small incision, with iridectomy sors, a subcutaneous flap was made over the pressed bridge of the nose. A piece of cellu about half an inch wide, an inch long, and a thirt of an inch thick, was sterilized by boiling for a minutes in soda solution. On taking it out of hot solution, the celluloid was readily molded the shape of the bridge of the nose. The cellu plate was then introduced through the incision, pushed upward until it occupied the space cor ponding to the subcutaneous flap. It was then ticed that the skin over the plate was almost wh The plate was removed, cut down a little on side, and re-introduced. The skin over it wa longer white, but normal flesh color. The inci on the under surface of the nose was closed with fine silk suture. To avoid pressure on the plate dressing was employed. Following the opera there was no pain or discomfort. There was a li swelling for a week or ten days, but the wo healed readily. Figure 2 shows the result sho after the operation. The patient recently prese himself at my office, and the ultimate result is better than shown in Figure 2. The man stated he had had not the slightest annoyance from plate at any time subsequent to the operation. method is, I believe, worthy of trial.

1001 Madison Avenue.

HE BLADDER IN HEALTH AND DISEASE, AS DEMONSTRATED BY THE CYSTOSCOPE.*

By HENRY G. SPOONER, M.D.,
NEW YORK.

HE study of modern cystoscopy began in 1879, hen Nitze introduced a method of lighting with an ectric lamp, having for a principle the direct light- g of the bladder. However, the Nitze-Leiter stoscope was too complicated and too difficult to

FIG. 1.

ep in repair to be of any use to the medical pro- ession.

In 1886-87 the Leiter incandescent lamp cysto- pe made its apprearance. This was a very good actical instrument.

Later modifications of the cystoscope have been de by Brenner, Boisseau, du Rocher, Fenwick, erbock, Wallace, Casper, Albarran, Nitze, Brown, d Lewis.

These cystoscopes may be divided into two groups: 1. Cystoscopes through which one looks directly the object, where no reversion of diameters occurs. 2. Cystoscopes with prisms inserted in the vesical d of the shaft, through which one sees the object ersed in the vertical diameter, but the parts of the

FIG. 2.

ld of vision seen at the right and left are actually these positions.

Nitze and Casper give courses of instruction on stoscopy every year. Each course consists of ht demonstrations, beginning the 28th of Sep- mber—and the 28th of February. Private instruc- n can be obtained at any time from Thumin or ossidlo. In Vienna cystoscopic instruction is ven by Von Frisch and Grünfeld. Nitze's courses e the most interesting, patients being referred to m from all parts of Germany and Austria. This tumn he showed two cases of carcinoma, one cyst the bladder on which he operated intravesically, e papilloma, and two tuberculous ulcers.

It is commonly stated that after eight or ten les- sons the student will have acquired sufficient skill to catheterize the ureters. This is an erroneous impression. Out of the twelve men who completed Casper's course this fall only two succeeded in catheterizing a ureter—one of these students had been a former pupil of Dr. Cabot and the writer.

Since Fenwick's work, published in 1889, there has been no textbook on cystoscopy published in the English language. Casper's work of 1898 gives the most concise statement of the subject. Nitze's book and atlas, to be published in Berlin this March, should be read by all doctors interested in diseases of the bladder.

FIG. 3.

While any one with a little practice and patience can learn to use the cystoscope so as to see tolerably well, it takes experience to interpret correctly what is seen. Only after continuous effort and a broad understanding of genitourinary pathology can judgment be obtained for the proper selection of cases for a cystoscopic examination.

Before attempting to use the cystoscope on the living bladder, the student should practise on one of the phantom bladders. It makes very little difference which one he chooses. An apothecary's mortar lined with bees wax, to which little pieces of colored sponge can be attached will answer just as well as a phantom bladder, with an expenditure of only twenty-five cents. Practice on the dead subject is unsatisfactory, as the ureteral walls have lost their elasticity, so that the cystoscope can very rarely be passed into the bladder without having the prism and lamp so soiled that it is impossible to see anything.

FIG. 4.

The cystoscope tolerates high temperatures very poorly, so that it cannot be rendered aseptic by heat. Albarran, Wossidlo, and Thumin use a 5-percent. solution of carbolic acid to sterilize the cystoscope. Nitze, Lewin, and Brown use a formalin lamp. Casper places his cystoscope in spiritus saponatus for five minutes before using.

Though the cystoscope is absolutely surgically clean, the urethra is very rich in bacteria. When a

*Read by invitation before the Medical Association of the Greater City of New York at the Academy of Medicine, January 11, 1904.

lubricant composed of glycerin, tragacanth, with the addition of a 1:500 solution of hydrargyrum oxycyanatum is used, the cystoscope is said to convey no microorganisms into the bladder. To prevent any possibility of infection the bladder is washed out after each examination with a 1:5,000 solution of hydrargyrum oxycyanatum.

As a matter of routine, Casper injects eight drachms of a 4-per-cent. solution of cocaine into the urethra with an ordinary clap syringe. The syringe is then filled with water and the cocaine solution is pushed into the bladder. Nitze uses the same solution of eucaine, as he considers this a safer proce-

FIG. 5.

dure. The bladder is then filled with a 2-per-cent. solution of boric acid. Nitze, Thumin, Casper, and Wossidlo all agree that 150-200 c. cm. is the proper amount to be introduced. However, the patient's feelings must be considered. It is useless to inject more fluid than can be retained.

The cystoscope, after the lamp has been tested to see if it is of sufficient brilliancy, is then introduced into the bladder like an ordinary metallic sound, with the greatest gentleness, to avoid any trauma of the urethra, as any blood covers the prism and adheres to it, so that when the bladder has been entered and the light turned on, only a diffuse red field of vision can be seen.

FIG. 6.

The Nitze cystoscope for ordinary use has a caliber of 21° F. The irrigating cystoscope as formerly made, had a diameter of 23° F., but as now made by Loewenstein has a diameter of 24° F. It therefore follows that the urethra must permit of the easy passage of a soft rubber catheter 21-25° F., before a cystoscopic examination can be made.

The bladder must be tolerant enough to hold at least 60 c. cm. When less tolerant than this no cystoscopic examination can be successful.

The bladder, as described in textbooks, is in a state of distention. When empty it lies in folds between the ureters and urethra. As the bladder fills, the ureteral openings are drawn away from the urethra into the cavity of the bladder, until full distention, when they have been drawn back 4 cm. The ureteral orifices lie in the interureteral line 2 cm. apart.

After the bladder has been distended to the extent of 150 c. cm. the cystoscope is inserted until the beak lies in the middle of the cavity of the bladder. The lamp is then illuminated, when a clear luminous field of vision of a light yellow color can be seen. If the bladder is dilated with urine the picture is more deeply yellow.

The knob on the handle of the cystoscope indicates the position of the beak of the instrument. As the shaft of the cystoscope is raised—lowered—moved laterally or rotated—all the internal surfaces

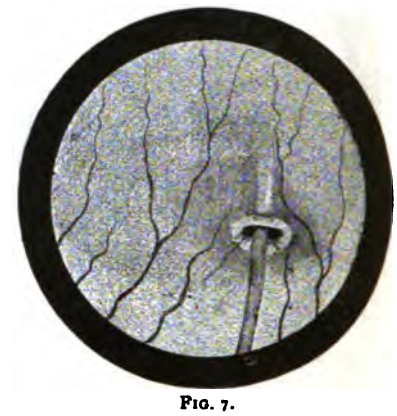

FIG. 7.

of the bladder can be seen with the No. 1 cystoscope of Nitze, with the exception of a small portion of the posterior surface.

With the beak pointing up, the cystoscope is elevated and slowly drawn toward the operator until a dark zone runs across the lower part of the field of vision, representing the neck of the bladder. As the cystoscope is further retracted, this darker zone can be seen to increase until it covers one-half of the picture, as seen in figure 1.

If the handle of the cystoscope is still further retracted, darkness ensues as the prism has been covered by folds of the prostatic urethra.

The light must be instantly turned off and the

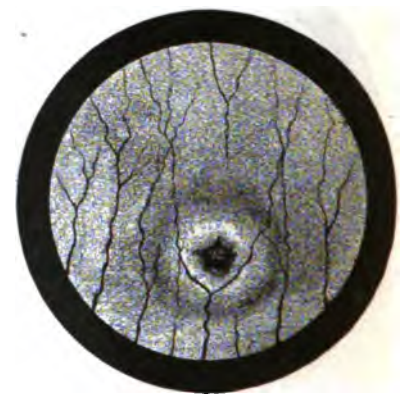

FIG. 8.

beak re-inserted into the middle of the cavity of the bladder.

The lamp is again illuminated and the cystoscope gently pushed back so that the prism is focused on a surface of mucous membrane—a pale pink surface shading on the orange—with parallel arterial branches is seen in the normal bladder if the light is sufficiently good, as shown in figure 2.

However it can be readily understood that the color of the healthy bladder presents variable differences. It differs with the individual and with the same individual in different localities of the bladder, also according to the brilliancy of the light, the distance of the prism from the object, the transparency of the fluid medium, and the diathesis of the patient.

When the beak of the cystoscope is rotated below 190°, and moved forward and backward, the interureteral line can generally be seen. This line represents the posterior boundary of the trigonum, and is formed by the light pink membrane of the bladder, shading into the more yellow mucous membrane of the trigonum, as shown in figure 3.

This interureteral line, when it can be found, is one of our most important landmarks, as the ureteral openings can be found at its lateral terminations.

When the bladder is not sufficiently distended, a brilliant light will not enable us to find the interureteral line or the ureters, as these will lie between

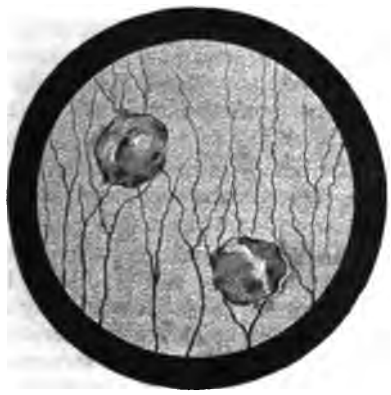

FIG. 9.

the folds of mucous membrane of the trigonum, as shown in figure 4.

The ureters can be found in a case of this kind by injecting more fluid, when the folds of mucous membrane will be smoothly stretched out, or by watching for the position at which drops of urine would exude from the ureteral orifice.

When the prism of the cystoscope is placed directly over the ureteral orifice, it can be seen in a luminous line in the form of a slit, generally situated on an elevation, as shown in figure 5.

At the moment when drops of urine exude from the opening, the ureter can be seen to bulge out in the surface of the bladder, as seen in figure 6.

When the ureteral catheter has been inserted, the

FIG. 10.

ureter can be seen to surround it, as shown in figure 7.

As we have seen, the ureteral opening consists of a slit, situated on a little round promontory in the great majority of cases. It may lie in a depression, but its form is, however, very materially altered after some general constitutional diseases, or after inflammation of the bladder.

In old men of atheromatous type, the ureter will sometimes be seen in the form of a gaping cleft, resembling the crater of an extinct volcano, as the contractibility of the muscular layers has been lost, owing to the degeneration of calcification (figure 8).

After inflammatory alterations the formation of white fibrous tissue can be seen to have contracted the opening leading to the hydro-and pyonephrosis.

The beginner in his anxiety to get as good a view as possible is apt to push the lamp into the mucous membrane of the bladder, causing a hyperæmic swelling or burn, as shown in figure 9.

The next attempt to see the bladder will be more difficult. These hyperæmic areas may serve for the growth of microorganisms that have entered the bladder from the urethra, ureters, or general circulation of the blood, thus causing a cystitis acuta suppurativa.

Any healthy bladder of young people between the ages of twenty-five and thirty years may be taken as a type of the normal. Just when the variations of

FIG. 11.

the normal bladder have advanced sufficiently to constitute a pathological condition is often difficult to determine.

The muscular frame-work of the bladder, when there is any hindrance to micturition, must do more work than formerly. Slightly trabeculated bladders are found in youth and old age. Such bladders cannot be considered as pathological, as the effort the bladder must make in cases of stricture of the urethra or enlargement of the prostrate gland to expel its contents, is in an increasing ratio—the bladder hpyertrophies more and more, until we get a trabeculated bladder, as shown in figure 10.

As the intravesical pressure is increased the urine is pressed in between the trabecula, and pouches of

FIG. 12.

the bladder may be formed that often assume a considerable circumference; 284 such cases have been reported in medical literature up to the present time. The urine remains behind in these pockets, particularly in those at the base of the bladder. In extreme cases a rupture may occur, causing a fatal peritonitis.

The normal bladder has an extraordinary vitality for the resistance of microorganisms, but when there is a congestion of its walls, or a hindrance to urination, it becomes receptive to the invasion of bacteria. The bacterium coli commune being the most frequent cause of inflammation of the bladder.

In cases of cystitis it is generally stated that the cystoscope is contraindicated on account of the in-

tolerance of the bladder. However, the intolerance of the bladder is in proportion to the extent and nature of the pathological changes. With patience and perseverance all the details of the inflamed bladder can be cystoscopically studied.

The parallel branches of the arteries that run only occasionally into each other in the normal bladder, can be seen to be greatly dilated, and all the smaller

FIG. 13.

branches that cannot be seen in a state of health become apparent. The mucosa is swollen, deeply congested, and hyperæmic. Here and there can be seen extravasations of blood or surface ulcers, as seen in figure 11.

Formerly gonorrhœal cystitis was considered to be an inflammation of the entire inner surface of the bladder. The cystoscope has shown that cystitis gonorrhoica is a localized process encompassing the neck of the bladder and the trigonum, but never spreading any further.

More frequently than was formerly supposed, cystitis tuberculosa is engrafted in the chronic gonorrhœal area.

Nitze, this autumn, demonstrated two cases to his class. Two cases were demonstrated by the reader, as shown in the MEDICAL RECORD of December 5.

Miliary tubercles are formed by the deposition and growth of the tubercle bacilli. These tubercles can be seen in the form of small round gray elevations, surrounded by hyperæmic areas. Later by the process of cheesy degeneration these tubercles ulcerate, and as their walls coalesce, extensive ulcerations of the mucosa and submucosa are formed.

After inflammation of the bladder, particularly the gonorrhœal form, the region of the trigonum shows a remarkable tendency to papillary proliferation. Small fibroma papillare (Virchow) can occasionally be seen in their incipiency.

As may have been noticed, we have principally considered the trigonum and ureteral orifices in this short paper, as the pathological changes occur in this region in the overwhelming number of cases.

Fenwick's statistics, based upon an examination of all the bladders contained in the museums of England, Scotland, and Ireland, are of interest. He found that single growths of the bladder occur in 86 per cent. of the cases in the inferior zone. They are found at the right ureteral orifice in 43 per cent.; at the left ureteral orifice in 26 per cent.; and on the interureteral line in 10 per cent. of the cases; 90 per cent. of the fibroma papillare or villous growths occur at the ureteral orifice.

In the region of the trigonum we find evident papilla and closed follicles, these being a transition to the structure of the glands of the urethra. The deeper layers of the polymorphous epithelium of the trigonum are of considerable interest, inasmuch as the spindle-formed and cylindrical cells have much similarity with isolated elements of certain malignant growths.

It is, therefore, from the histological formation of the trigonum, easy to understand why this region should show such a tendency to papillary proliferation.

As growths of the bladder increase in size for a long time without causing the patient to suffer in any way, an early diagnosis can only be acomplished by a cystoscopic examination.

In four instances I have seen small villous growths succeeding an old gonorrhœal inflammation of the bladder.

The most interesting case is that of a motorman, twenty-six years old, who had had a chronic gonorrhœal urethro-cystitis. Last March fibroma could be seen growing from the neck of the bladder, as shown in figure 12.

Last September papillary proliferation had occurred on the region of the trigonum, as shown in figure 13.

These small villous growths are the starting points of most of the tumors of the bladder. By further papillary proliferation these growths may assume the shape of a cauliflower, or as the proliferations extend all the details of their beautiful structure may be studied as the filaments float in the fluid of the bladder.

It is unfortunate that the macroscopical appearance of these growths do not accurately correspond to their histological formation. All that can be said is that the single growths with small pedicles are mostly benign. Tumors that spring from a broad base are generally malignant.

The most important concretions are those of the urinary passages. In the bladder the stroma of concretions are produced by parts of the mucous membrane of the urinary passages, occurring preferably where inflammation has caused collections of mucous and epithelial cells in the bladder.

If there is a uric-acid diathesis concrements will be composed of uric acid. It the urine decomposes in the bladder, producing triple phosphates, concretions can be formed of this.

Foreign bodies introduced into the bladder may form calculi by becoming encrusted. As a rule the ordinary metallic searcher reveals the presence of

FIG. 14.

stones, without the use of cystoscope. However, cystoscopic examination will give us an exact knowledge of the existing conditions. Small concretions may be overlooked. The cystoscope may reveal their presence.

To determine the extent of mechanical hindrance to urination formed by hypertrophy of the median lobe of the prostate, the cystoscope is our only guide (figure 14).

A Simple Method for Carrying Out the Diazo Reaction.—Bondi describes a simple method for performing this reaction which is convenient, is applicable when only a few drops of urine are available, and can quickly be carried out on a large number of specimens. The reagents are all used in the customary concentration, but the test is made on filter paper instead of in test tubes. A drop of the suspected urine is allowed to fall on a double piece of filter paper and with a glass rod a drop of ammonia is deposited on the same spot. The rod is wiped off and is moistened with a little of the sodium nitrite solution. It is held horizontal and a drop of sulfanilic acid solution is allowed to run down it till it mixes with the sodium nitrite at the end of the rod. The moist spot on the paper is circumscribed with the wet end of the rod and a red coloration appears when the reaction is positive. Urines which do not give the diazo reaction produce only a faint yellowish color. A large number of control tests have established the accuracy of the reaction, which gives the red color only in cases in which the foam would be pink.—*Zentralblatt für Innere Medizin*, No. 10, 1904, March 12.

The Etiology of Seasickness.—Binz reiterates his former statements to the effect that seasickness is the result of a state of cerebral anæmia induced through an irritation of the vasomotor centers caused by the motion of the vessel or through psychical stimuli. The facial pallor which is the earliest symptom of the malady reproduces the vascular conditions within the skull, and observations recently made by Kramer substantiate this view. This writer made ophthalmoscopic examinations of forty patients and found that the vessels were small and contracted and that the choroid was as pale as is usually the case in those who have suffered severe loss of blood. By a series of observations with the "onychoscope," a form of manometer intended to indicate the fluctuations of blood-pressure in the distal phalanx of the finger, Binz came to the conclusion that rhythmical movements of an extremity caused the vessels of the part to be less completely filled, but that there was no ground for the theory that seasickness was due to alternations of anæmia and hyperæmia of the cerebral vessels produced by wave-like fluctuations of the blood column.—*Zentralblatt für Innere Medizin*, No. 11, 1904, March 19.

Tuberculosis of the Parotid and the Possibility of Infection through the Tonsils.—George B. Wood has collected nine cases of tuberculosis of the parotid. Three were infected through Steno's duct; one from the neighboring lymph glands; one by the blood current; in four the origin of infection was obscure. In the author's case the infection was probably from the submaxillary gland. The author has tabulated 1354 examinations of the tonsils for tuberculous conditions. Seventy-three cases gave positive results (5.4 per cent.) Tuberculous changes in the tonsil are rarely noted microscopically. A series of cures show that about 65 per cent. of cases of pulmonary tuberculosis have a similar affection of the tonsils. The author thinks that the positive results should have more than proportional weight, and that tuberculosis of the tonsil is much more frequent than the cases would show. Tuberculosis of the cervical glands probably nearly always results from infection of the pharangeal and faucial lymphoid tissues. It is possible that the bacilli can pass directly without local infection from the tonsillar crypts directly into the lymphatics.—*University of Pennsylvania Medical Bulletin.*

Craw-craw.—J. Dencer Whettles states that this disease is due to general infection by a nematode. He thinks that the infection is brought about by the introduction of the nematodes themselves or their ova into the blood through either the stomach or the intestinal wall, the carrying medium being milk, in which the parasite has been found several times. He thinks the habit of mixing the various samples of milk at the distributing centers in order to raise the pure milk to the legal standards gives every opportunity for the dissemination of parasites among large communities which may have been present in only one of the samples. In Birmingham the evident symptom is signs of rubbing of the sides of the nose and eyes, and case after case of this can be seen in the streets. The shampooers at the Turkish baths state that the effects are seen in five out of six. It is commonly seen in the theaters. The parts attacked in order of degree are, summit of the shoulder, flexor side of the arm, flexor side of the thigh, hips, chest, dorsal border of the fingers, and the face, chiefly the nose and eyes. The papular variety of the affection is the most abundant, appearing, soon after the commencement of the irritation, in the form of small nodular swellings about the size of No. 8 shot beneath the skin. These enlarge after being scratched and the irritation increases in proportion.—*Treatment.*

Gonorrhœa in Women.—C. Jeff. Miller emphasizes the importance of more rational treatment of this affection and better observation and diagnosis during the latent period. He thinks that the onset of the disease may be trivial, passing quickly into what appears to be an ordinary leucorrhœa which women too often ignore; that the subjective signs are fleeting in character and may disappear while the disease is at its height, and that in primary cervical infection, no subjective sign may be present until the endometrium and higher structures are involved. The treatment requires an early diagnosis while there is still a recognized point of primary infection, and resolves itself into the application of active germicides and to a close personal attention to every detail. Care of the patient should be continued until there is no further evidence of the disease shown by clinical and microscopic tests. The acute form of the disease is rare compared to the slowly developing condition which may have its few acute signs buried under a trivial leucorrhœa years previous to the first sign of real trouble. A young woman marries and notices shortly afterward a trifling leucorrhœa, which gradually increases in intensity, and is accompanied by tenderness over the ovaries and pain on physical exertion, later lassitude, extreme nervousness, and aching of the thighs and legs.—*New Orleans Medical and Surgical Journal.*

Excision of a Tuberculous Mass from the Liver.—R. R. Rome presents the history of a patient, a woman of forty-two years, whose symptoms began with a severe pain in the right lumbar region giving a pulling sensation and preventing her from walking erect. This continued at intervals for some three months, when she was seen by the author. An enlargement was detected at a point midway between the cartilage of the tenth rib and the crest of the ilium. Abdominal incision revealed the fact that the appendix was chronically inflamed and it was removed. The gall-bladder was found contracted and retracted; no calculi could be detected. Directing search by the aid of the sense of touch along the edge of the liver, it was found that two and one-half inches of intestine were adhered to the liver. After separating the adhesions and freeing the bowel, a tuberculous tumor the size of a goose-egg was found in the lower right lobe of the liver. The surface of the liver corresponding to the tumor was firmly adhered to the parietal peritoneum. After freeing these adhesions, it was apparent that the section in which the tumor was situated could be removed in the shape of a wedge or triangle. This was mentally outlined, and heavy catgut sutures were introduced, beginning at the apex of the triangle and passed through the thickness of the lobe; the needle was reinserted and brought out opposite the first free end and left untied. Sutures were introduced in this manner half an inch apart and half an inch from the margin of the triangle. After inserting a sufficient number of sutures, the wedge was cut away with scissors, and the surfaces of the liver immediately brought together and the sutures tied. Approximating the surfaces in this way promptly checked the hemorrhage. The patient made a good recovery.—*Annals of Surgery.*

THE MILK SUPPLY OF CITIES.

THE question of the milk supply of cities is one that appeals intimately to all classes of society, from the highest to the lowest. In order to bring up children healthy, pure milk, or at least fairly pure milk, is a *sine quâ non*. Therefore the necessity of agitating for such an article is obvious, and it is, moreover, the bounden duty of health officers, and to a lesser extent of physicians generally, to use every endeavor to obtain this result. The realization of this object is by no means easy, for the entire matter is hedged in with various difficulties. Nevertheless, persistent harping upon the same string cannot but have a favorable influence, and should arouse the community at large to a recognition of the surpassing importance of the subject.

The *Albany Medical Annals*, March, is devoted to a discussion of the milk supply of cities, to which many well-known writers have contributed. The first communication is from the pen of R. A. Pearson, Professor of Dairy Industry, Cornell University, who deals with the production of sanitary milk from the producer's standpoint. The writer is of the opinion that there are at least four influences that are respected by milk producers, and he proceeds to consider them briefly. They are: (1) Legal regulations; (2) Intelligent public opinion; (3) The example of high-class dairies, and (4) Endorsement by responsible persons.

Mr. Pearson shows that reasonable and well-enforced laws and ordinances suit all persons concerned. The dairymen appreciate them because they see the advantage of suppressing undesirable practices, while strict and well-enforced milk regulations increase public confidence and at the same time increase the demand for milk. Intelligent public opinion is a strong factor in procuring a pure milk supply, and is an influence that will be respected by dairymen. Consequently the inhabitants of towns virtually hold the key of the situation, if they insist upon having milk of good quality, undoubtedly their demands will be fulfilled.

The writer thinks that another agency working toward better milk is the Milk Commission. Such commissions have good effects by reason of their educational agency. There is one point, however, in connection with the supply of better milk which needs to be well understood—namely, that there must be a willingness on the part of the purchaser to pay a fair price for quality. The dairyman in order to produce milk so as to avoid unnecessary contamination, must spend more money to bring this result about, and will have to increase the price. In short, the general public and the dairymen must work together. Mr. Pearson rightly lays much stress upon the beneficial part the physician can play in the rôle of educator, and urges the medical profession to take an active interest in the procuring of a pure milk supply, and by pen and voice to educate the public as to the value of uncontaminated milk.

The next article is by Dr. Charles Harrington, Assistant Professor of Hygiene, Harvard Medical School. This writer says that the first question is, How shall we ensure the public against the consumption of milk rich in bacteria? and answers his question thus: "Now there are two ways of producing milk with comparatively few organisms per cubic centimeter, (*a*) by subjecting those already present to the destructive influence of heat, *i.e.* by pasteurization or sterilization, and (*b*) by preventing their growth from the beginning." Dr. Harrington is not in favor of the first two methods, but insists that strict cleanliness is the essential procedure. By these means bacterial growth can be almost entirely prevented from the beginning, and he is of the opinion that regulations enforcing the same should be framed.

Dr. Rowland G. Freeman, Lecturer on Pediatrics, University and Bellevue Hospital Medical School, contributes an article on the "Contamination of Milk," in which he treats of the various sources of milk contamination.

In the discussion which followed the reading of the foregoing papers Dr. Craig took a prominent part. He summed up his ideas as to the conditions necessary to provide a better milk supply for cities thus: That the practical points to be dealt with were on the one hand from a commercial standpoint and upon the other in accordance with the dictates of charity. The writer believes in the establishment of a "milk trust," or rather a single milk station, with proprietary interests in the muncipality. "In this way only," he says, "Can we succeed in having a properly standardized milk eventually adopted for public use. The other method of supplying standardized milk is through charitable organizations.

The discussion was closed by Dr. Cook, who held that the cause of much milk contamination in New York State was the unhealthy condition of the cows themselves. He further said that there was no test in New York State, as in the adjoining States, to prevent tuberculous cattle from being brought in. The speaker's theory with regard to the steps to be taken to obtain pure milk is somewhat as follows: First a healthy cow; then proper surroundings; then a clean stable with a proper amount of air space; then a healthy attendant; then clean utensils; then as soon as the milking is completed the milk to be reduced to a certain temperature and held at that temperature till shipped. It should come to the middle man in a condition in which it has not been allowed to undergo any bacteriological change. Then it should go into a room at a certain temperature, bottled at a certain temperature, and kept at that temperature till it is delivered to the consumer. Then the consumer should be educated up to the standpoint that it should be kept at a certain temperature till it is used. Dr. Cook's view is that the first and essential point is to have healthy cattle, for so long as cows are diseased it will be impossible to procure pure milk.

E AGRICULTURAL DEPARTMENT AND WATER PURIFICATION.

E Agricultural Department at Washington has ated a veritable public sensation by the announcent of a new method of purifying drinking water by addition of a diluted compound of sulphate of per and a certain lime salt, thereby not only deying the vegetable scum on the surface of reserrs and stagnant pools, but also killing all the arial and typhoid germs which are likely to be sent. The novelty of the proposition is only alled by its absurdity.

he possibility of affecting the desired result is not y contrary to all scientific views on the subject of er purification, but singularly lacks any practical lication of the plan to the actual needs of the ation.

he claim is that the dead product of chemical ion deposits itself upon the bottom of the pond by so doing makes the surface pure. It is exnely difficult to understand how any improvent on actual conditions can thus be made by ely substituting for living aquatic vegetation ded material which is simply out of sight. To the inary mind this would appear rather to increase difficulty than to remedy it.

t is yet to be proven that ordinary aquatic vegeion is actually harmful to drinking water. Its ence is simply an indication of stagnation rather n unhealthfulness, as even running water cons the algæ in great quantities. Of course this is rgument against the rippling stream as furnishthe typical, potable water, but the second choice y no means such a forlorn expedient as might erwise appear. In any event there should be no d for stagnant pools of any sort even from an hetic point of view, as simple drainage is always ilable; nor should scum be allowed to accumuwhen it can be so easily disposed of by ordinary ation. All that is really required in the latter ance is mechanical separation, which is by all s the most effective method for preserving the ual life of the water. To add chemicals of any d to a water is to contaminate it in a greater or er degree.

he promise to kill the typhoid germ by such ns is an absurdity on its face. Even if a chemi mixture could accomplish the purpose it would essarily be of such strength as to make the water t for drinking purposes. We could hardly ext more from this new mixture than from some of more powerful bactericides that have been used the typhoid bacillus, and in vain.

So far it has been admitted by scientific experimenters that thorough boiling of the water is sure death to this microbe, and pray, why is it necessary, by adding medicine to our drink, to eschew a simpler, safer, more available, and more effective plan of disinfection?

The new compound, whatever it actually is, may be useful in indirectly exterminating the mosquito by depriving it of its food, but obviously the plasmodium itself cannot be reached directly, as it is not yet proven that the parasite actually breeds and propagates itself in swamps. All that is positively known at present is that the mosquito and man are the only parties concerned in the development of malaria. All this would seem to prove that the chemist of the Agricultural Department is a trifle beyond his calculation of any real good that may come from the latest widely-heralded discovery in disease prevention.

THE RESIGNATION OF PROF. WM. T. BULL.

THE resignation of Prof. William T. Bull from the chair of surgery in the College of Physicians and Surgeons, which he has so long filled with such great credit to himself and to that institution, is a notable circumstance bearing on the purely individual reasons for its occurrence.

It was simply a question of the man and the hour meeting on the common grounds of adaptability. In the midst of his great usefulness to the school he voluntarily leaves his duties to his successor and retires with his well-won honors, and in the zenith of his fame as one of the representative surgeons of his day. From such a point of view he will be remembered by his pupils as one always up to his work and thoroughly alive to all the onerous requirements of his office.

Aside from the example this may be for others under like conditions, it brings with it a becoming regret that he could not for awhile longer at least have continued in his office. But at no better time, considering the other exacting professional duties constantly awaiting him, could the change have been made. As it is, all that his numerous friends can wish for him is continued health and growing prosperity in larger fields.

JAPANESE HOSPITAL SHIPS AND RUSSIAN MILITARY MEDICAL SERVICE.

IN the *Journal of the Association of Military Surgeons* for April appears an article on Japanese hospital ships from the pen of Dr. Tessier, médicin sanitaire maritime, contributed to a recent number of Le Caducée, and translated by Lieut. Charles Norton Barney, Medical Department, U. S. A.

The main part of this narrative is as follows:—As soon as the Treaty of Shiniouoseki was signed, the Japanese Red Cross Association had two ships specially constructed for ambulance and hospital service in time of war. These two ships were built on the Clyde, Scotland. Both were constructed on the same plans. Each has a displacement of 2,700 tons, a draught of 6 meters, length 95 meters, beam 12 meters, and a speed of 15 knots an hour. On the upper deck are the salon and cabins, a disinfecting room, laundry, galley, hoist, lamp locker, bath rooms, and water closets; three of the staterooms on the deck are assigned to the Red Cross delegate and his secretary, two to officers of the navy and interpreters, one to chief medical officer and others to the ship officers generally. In the 'tween-decks are the staterooms of the junior medical officers, of the pharmacists, and of the female nurses, and a mess room for the latter. The hospital, which is situated in this part of the ship, is composed: aft, of several staterooms holding in conjunction forty-five cots reserved for officers; further forward, of staterooms and a large ward capable of holding 115 non-commissioned officers and soldiers. Still further forward, and separated from the others by a bulkhead, is a ward of forty-two cots for contagious cases. There are also

on this deck operating rooms, dispensary, radiographic room, laboratory, bathrooms, etc.

The lower deck comprises the quarters of the hospital corps, a mortuary, an ice plant, a refrigerating room, a baggage room, and store-rooms; further forward, machines for cooling and compressing the air, used in the artificial ventilation of the ship, and the boilers, and way forward the quarters of the crew.

The medical personnel embarked includes, among others, a delegate from the Red Cross, a chief medical officer, three junior medical officers, a pharmacist, and an assistant pharmacist, a secretary or chief clerk, a chief of female nurses, two hospital sergeants-major, two female nurses (chiefs of squad), two hospital sergeants, nine female nurses, twenty-eight hospital corps soldiers, an instrument sharpener, a laundryman, interpreters, etc.

These ships are named respectively Hakuaï-Maru and Kosaï-Maru. The former was on her way to Shanghai, when she received orders, June 28, 1900, at the beginning of the international intervention in China, to get ready for active service. After being fitted out at Yokohama she started for Taku on July 7. Between this date and end of April she made seven trips from China to Japan, transporting in all 1,538 patients. The latter ship made likewise seven trips from China to Japan and transported 1,328 sick. These ships carried to Japanese military hospitals, patients not only from the Japanese forces, but also some from others of the allied forces.

Dr. Tessier also discusses in Le Caducée Russian military medical affairs. Russia has no hospital ships, but as her fleets are blockaded, up to the present this need has not been felt. It is believed, however, that in the case of hospital ships being required, that the Russian Red Cross Society would meet the exigencies of the situation in this particular. Great enthusiasm prevails to-day in Russian Red Cross circles. The Russian military Red Cross has now mobilized twenty-six field hospitals with 5,050 beds. Numerous sanitary Red Cross trains have left St. Petersburg for the far east. Each of such trains comprise eight cars for the sick, four of which are reserved for the severely injured and four for the more slightly wounded. There is also a cook's car, a medicine car, an operating car, two cars for linen and clothing, and a car for wounded officers. It is more than probable, thinks Dr. Tissier, that the Russian Red Cross will take a prominent part in the sanitary service in Manchuria and assume a position of much greater importance than is allowed to it by the regulations of other European armies.

The military medical organization of the Russian army is unwieldly and in many ways badly arranged, so that there will be full scope for the services of the Red Cross.

The hospital ship service of Japan is thoroughly up to date, and their ships were probably the first built intended wholly to serve as floating hospitals and ambulances. This is but another of the many proofs recently manifested of the extraordinary adaptability and progressiveness of the Japanese. Their military Red Cross Service is also splendidly equipped and in every way fitted for its duties, and will compare favorably with that of any great power. The medical and surgical features of the war between Russia and Japan will undoubtedly be of the greatest interest, and will serve as an object lesson to the medical departments of all armies.

Our Special Reports from the Isthmus of Panama.

Attention has been called on several occasions in the Medical Record to the sanitary conditions of the country through which the proposed Panama Canal will pass, and it has been urged that, before work is even commenced on that undertaking, vigorous efforts should be made to render the route and its vicinity more healthful. Preliminary steps are now being taken with this object in view. Colonel W. C. Gorgas—whose work in Cuba fits him admirably for the task—has gone with the Commission to Panama in the position of sanitary and medical adviser. The local situation will be carefully studied, and plans prepared for the sanitation of the canal zone and of the cities of Panama and Colon themselves. Health conditions along the canal route are not nearly so bad as they are popularly believed to be. The greater part of the country the canal will traverse is fairly high, well above the sea level. At the ends, however, low-lying, disease-breeding swamps extend, in which numberless mosquitos exist. The marshes, therefore, near Panama and Colon must be drained. In fact, proper sewerage and drainage systems, and an adequate supply of pure water, are undoubtedly essential needs, and the introduction of these measures would probably make of the Panama Canal route a locality in which white men, taking necessary precautions, would be able to live in as good health as those of the Caucasian race usually enjoy in tropical countries.

Arrangements have been made with our special correspondent accompanying the expedition, whereby the Medical Record will receive from time to time accurate reports at first hand of the doings of the Panama Commission, and especially with regard to any arrangements or suggestions which may be made respecting sanitary affairs.

The Curse of Corsets.

Dr. Arabella Kenealy contributes to the *Nineteenth Century and After* an article with the above title. The effusion is a violent diatribe against corsets for women, and the writer expresses her opinions in extremely plain language. In the early portion of her remarks she uses this epigram: "Dress has been given to women to conceal her deficiencies, and to this end she employs it, beauty and dress assuming generally an inverse ratio one to the other." The writer declares that in Great Britain the habit is immensely on the increase, and that tight-lacing once confined to the upper classes now permeates the humblest.

Dr. Kenealy describes in the following vigorous language the effect of the corset on the girl when she rises in the morning: She encases herself in an abnormality of steel and whalebone, compressing vital organisms in an unyielding grip. The resulting sense of constriction, more irksome, as every woman knows but too well, in the morning, where it does not induce actual nausea, at all events occasions a feeling of pressure destructive of appetite; so that after a fast of some twelve to fourteen hours the girl, whose growing, hungry tissues clamor for fresh supplies, is unable to take the food her system badly needs to start the day upon. Or if she takes it the cramped organs can but ill assimilate it. The storage power of the liver is diminished, the blood currents are impeded and become sluggish, the lungs shrink, and the starved blood cannot nourish the tissues. The abdominal muscles are atrophied, and later in life will probably yield altogether, the woman becoming the shapeless personage we regard as the norm of middle age."

Dr. Kenealy refuses absolutely to listen to the cry that stays are not tight. She says that the stays are

indeed tight is shown by the fact that although the physique and internal organs expand in every other direction, the waist of the adult woman is actually less than that of the girl between ten and twelve. . . . The female waist is naturally two inches larger than that of a male of corresponding height and weight.

The article closes with these brutally outspoken words, words that no one but a woman would have dared to use. "There is no doubt that dress is the calamity which covereth multiple previous deficiencies. The average woman, clothed as fashion clothes her, presents, I confess, an exterior pleasing to our artificial and acquired tastes. Unclothed—alas! alack is that to make the physiologist and artist weep." The fact is undeniable that tight lacing is injurious to the health, and it is also true that many women do lace tightly. But Dr. Kenealy in her article allows her feelings to carry her away, and lapses into many indiscretions of speech. The rising generation of girls, at least those of the Anglo-Saxon race, and of the well-to-do classes, are physically bigger and stronger than were their grandmothers, and the result is due to the healthy out-of-door life which the majority of them lead. As to the girls belonging to the working class, it may be as Dr. Kenealy says, that the practice of tight lacing is increasing among them. If so, they should certainly be warned that the custom is a pernicious one, and also be reminded that the Greek sculptors, the greatest the world has ever known, took as their models for the highest type of female beauty, women with by no means small waists, but those with waists proportionate to their build.

ASIATIC CHOLERA IN THE PHILIPPINE ISLANDS.

Bulletin No. 2, published by the Board of Health for the Philippine Islands has recently been issued. The pamphlet is on Asiatic Cholera in the Philippines and is written by Dr. Thomas R. Marshall, Chief Health Inspector there.

The disease has for months been the prevailing malady in the Philippine Islands, and the present infection is believed to have entered through the port of Manila in March, 1902, emanating from China.

Water is probably the most frequent means of conveying cholera to man. Generally speaking, the water supply of the Philippine Islands is bad. In Manila itself, aerated waters and other bottled drinks, and sorbete, are likely to convey cholera infection. With regard to the contamination of food, Dr. Marshall thinks that, probably flies play an important part by conveying the cholera spirillum from evacuations or dead bodies. In March, 1902, the writer found on the legs of flies caught around cholera cases an organism identical morphologically with the cholera vibrio. Dirt may be a means of infection, also contact with infected vessels, clothing, bedding, etc., or the hands of persons attending the sick.

Dr. Marshall summarizes the usual sources of infection as follows: (1) From drinking water infected with cholera excreta. (2) From using infected water for washing cooking utensils, dishes, etc., on which food is served, or for washing cloths with which utensils, dishes, etc., are wiped. (3) From flies and possibly other insects which convey the spirilla from infected dejecta to food. (4) From nurses, attendants, washerwomen by direct conveyance of infection from the patient or his clothing to the mouth. (5) From food accidentally contaminated by handling—vegetables and fruits sprinkled with infected water or manured with human excreta. This practice, so common in the Philippines, particularly with Chinese market gardeners, is exceedingly dangerous and should be prohibited. (6) From fish and other river and sea food taken from infected waters. (7) From dirt or air contaminated by infected dejecta. This means of infection is probably very infrequent.

The writer discusses preventive measures at some length. He states in part that in his opinion, it is an indisputable fact that an experienced, well-organized and equipped health board can, with the aid of the people, prevent the spread of cholera, and even its introduction. The most effective modes of disinfection are then described in detail, and Dr. Marshall concludes by laying down the following simple rules for observance on the occurrence of cholera in municipalities and barrios: (1) Drink only boiled, distilled, or well-known bottled waters. (2) Avoid eating anything likely to produce diarrhœa, particularly uncooked vegetables and fruits. Should diarrhœa appear, immediately secure medical treatment. (4) If it becomes necessary to attend cholera hospitals or persons sick of cholera, be careful to disinfect the hands before eating or smoking or leaving the infected area. (5) Keep the stomach acid by occasionally drinking lemonade, lime-juice, or water containing a little diluted hydrochloric acid; cholera spirilla cannot live in an acid medium. (6) Correct any insanitary condition about the premises, pay especial attention to drains, latrines, cesspools, or any filthy locality; have them cleaned and (if necessary) disinfected, and their contents effectually disposed of. If the house contains plumbing or sewerage, have it examined for leaks. Guard carefully the water supply.

As to the germicidal treatment, the writer says "various remedies directed to the destruction of the cholera vibrio in the intestinal canal have been tried, also drugs designed to counteract the physiological effect of the cholera toxin, but so far without sufficient clinical proof of value. Benzoyl-acetyl peroxide and the salts of silver have been extensively used in the Board of Health hospitals in Manila and favorable results therefrom are claimed."

Since the disease broke out in March, 1902, 5,023 cases, with 3,886 deaths, have been recorded in Manila, and 141,712 cases, with 90,745 deaths, in the provinces; while there is every reason to believe that the provincial figures do not represent more than half of the actual number of cases and deaths which have occurred.

Owing chiefly to the filthy and insanitary habits of the natives and their custom of eating raw fish and decomposed food and of drinking polluted water the disease has spread with great rapidity among them.

The problem of how to successfully fight Asiatic cholera in the Philippine Islands is the most important of the many which confront the health boards in our far Eastern dependencies. The solution of this problem too will tax the energy and patience of American surgeons to the utmost and, although in time the desired object may be attained, yet judging from the experience of the British in India and elsewhere, this result will only be reached by the exercise of the most rigid preventive measures, measures extremely difficult effectively to carry out among races like the Filipinos.

TYPHOID FEVER AT LEADVILLE, COLORADO

An epidemic of typhoid fever occurred in Leadville, Col., of which the onset was very sudden and the origin somewhat obscure. The Colorado State Board of Health, Sanitary Bulletin, January 31,

published an account of the manner in which the epidemic in Leadville was initiated. The two first cases of typhoid fever came from Breckenridge in August, 1903, and were taken to St. Vincent's Hospital. This hospital is situated on some of the highest ground in Leadville, and the drainage runs toward the center of the city. The sewage from the hoppers, sinks, etc., before emptying into the sewer in the street, flows through a settling tank, where heavy matter is allowed to rest, and the liquids pass off into the sewer. The tank is made of brick and mortar, not cemented inside or out, and, consequently is not waterproof. The theory of the State Board of Health as to how the epidemic originated in Leadville is as follows: Stools, which were not disinfected from these first few typhoid-fever cases in the hospital, reached the settling tank. Hence seepage occurred downward toward the street until the water main was reached. This brought the seepage from the cesspool, contaminated with the germs of typhoid fever, to the water main. On December 5 the main was drained in the vicinity of the hospital. As soon as the mains were drained, a vacuum occurred, and then the seepage would flow into any crack in the main with which it came into contact. When the water was in the main, the pressure would be so much greater inside the pipe than out that seepage could not occur. But when the main was drained the pressure would be reversed. In a town like Leadville, it is not an uncommon thing, owing to the mining that is going on in the town and its vicinity, for the water mains to become injured from the settling of the ground, resulting, of course, in more or less leakage. Therefore, it would be an easy matter for contaminated sewage to come into contact with one of those leaks, and for the sewage to enter the main at the time it was drained. It is believed that this is what happened in Leadville, and in this manner the water became contaminated. This view was borne out by the following facts: The water supply of Leadville, before it reaches the city mains, is as pure as any water supply in the State of Colorado. Nothing but contaminated water could cause so large a number of cases of typhoid fever, milk flies and vegetables being excluded, and consequently, as typhoid fever comes from typhoid contamination, such contamination occurred somewhere inside the city mains. In view of the fact that the mains were being drained for repairs; the stools from the first cases of typhoid fever were not disinfected; that they were allowed to flow into a settling tank that was not waterproof; and seepage could easily reach the water mains; that the greatest number of cases occurred in the district lying below the hospital, which would receive this contaminated water, while other districts which did not receive it had but very few cases, all point to this method as being the one which contaminated the water supply.

Midwives Bill in England.

The incapacity of the British midwive has long been a potent source of danger to the indigent mothers of England, as well as a disgrace to an enlightened country. A large proportion of the poor of Great Britain are not able to afford the services of a physician when their women are confined, but must rely upon the help of the midwife. Any woman could, without any training whatever, take up the calling of midwive, and until the passing of the Midwives' Act, many entirely uneducated and incompetent persons did this as a means of adding to their earnings. The result of the laxity of the regulations as regards this matter may be easily imagined. Of late, however, the British medical profession have awakened to the gravity and also to the anomaly of the situation, and the midwives' bill to remedy the defects of the present lack of system became law.

It is further proposed in England to establish a national training school for district midwives. At a meeting held recently at the London Mansion-house in behalf of the above scheme the Bishop of London —one of the most practical divines who has ever ruled over that see—delivered himself of some common-sense remarks regarding the existing state of affairs as to parturient women. He remarked it was an astounding fact that practically until 190 Great Britain was the only nation in the whole of Europe which permitted anyone without training to carry on the work of a midwife. About 60 per cent of the mothers of England were dependent in the hour of trouble upon inexperienced and untrained help. He was, therefore, not surprised to hear that 3,000 women a year in Great Britain died during their confinements in the immediately ensuing period, who need not have died if they had had qualified assistance. At the same time one-third of the inhabitants of our blind asylums would not have been there had their eyes been properly treated during the first hours of their life.

Probably the scarcity of trained assistance was greater in the country districts than elsewhere. The shortage of children throughout the Anglo-Saxon race was going to be one of the great problems of the future unless it were stopped. If in addition to this state of things those who were born were treated in an unskilful and clumsy way, the future of the race was indeed in peril.

The proposal suggested for the training of women in all that appertains to midwifery work, is that a small general hospital should be established with a maternity annex in a neighborhood already in need of such an institution. This to be recognized as a national training school for district midwives; that in the wards, educated women would receive training in general and monthly nursing; that the training should be supplemented by instruction in simple hygiene, sanitation and physiology, the elements of cooking, the laws of infant breeding, the necessity for vaccination, etc.; that the course should in no case last for less than two years; and that the midwives should return every third year for reëxamination and instruction in those advances of modern obstetrics which immediately concerned their work.

The foregoing plan is thorough and will doubtless result in the education of a number of well-trained midwives. Such hospitals, however, should be established in the large towns in every part of the country. In the United States the custom of employing the services of midwives is very prevalent, as the fees of American physicians for doing this kind of practice are prohibitive in the case of the poor. It cannot be said that the supply of trained midwives is nearly equal to the demand—indeed, in this country the situation in this respect is almost if not quite as bad as in Great Britain. Consequently it behooves the members of the medical profession to look to this matter, and to endeavor to devise a scheme whereby a poor woman may be enabled to undergo her confinement with the safety, more or less guaranteed by the employment of skilled help.

Threatened Strike among the Drug Clerks of Chicago.—It is announced that the drug clerks in Chicago employed by the Wholesale Druggists' Association have demanded a 5 per cent. increase in wages, which the employers have refused. This refusal, it is thought probable,may lead to a strike in which 1000 clerks will be involved.

News of the Week.

e Abolition of the Office of Coroner in New York ty.—The Elsberg Coroners' bill was passed in the w York State Assembly on April 8. The bill es away with the office of Coroner in New York ty, placing their duties in a board of Medical aminers under the Department of Health.

Students at the Medical School of Columbia College ject to Tuition Fee.—A petition has been presented the authorities of Columbia University, signed the medical students, protesting against the ent increase in the tuition fees. The petition s stress on the fact that the students already triculated in the school do not consider that the posed change applies to them. They argue that the past, when fees were to be advanced due ice was given, and those who had already matric- ed were not affected. They also assume that statements made in the announcement of the dical School, the university practically contracted educate them for four years at the cost of $200 annum. The petition says that by increasing fees, all the calculations of the men who are porting themselves will be upset.

esolutions on the Death of Dr. John Metcalfe k.—At a special meeting of the Class of 1899 of Cornell University Medical College, held April 4, 4, the following resolutions were unanimously opted:

"*Whereas*, We have learned with deep regret of death of our class-mate, John Metcalfe Polk, D.;

"*Resolved*, That in the death of Dr. Polk the class 1899 loses one of its most promising members, that the medical profession is deprived of one ose career opened with unusual brilliancy.

"*Resolved*, That we tender to the family of our fellow-student our heart-felt sympathy in their at bereavement.

"*Resolved*, That a copy of these resolutions be warded to the family of our deceased class-mate, that they be sent for publication to the medical rnals of this city and to the Cornell Alumni ws.

"FREDERICK L. KEAYS,
R. J. E. SCOTT,
WILLIAM J. JONES, Jr., } Committee."

entence of Dr. Conrad.—Recorder Goff, on April entenced Dr. Conrad, convicted of attempting an al operation, to an indeterminate sentence of more than two years nor less than one year in tate prison. The Recorder said, that as this the first case of conviction for attempted viola- of the law, he would be pleased if a certificate reasonable doubt could be obtained, so that the stions involved might be settled by a higher tri- nal.

o Aid Sick Children.—At a meeting of the Speed- l Society for Sick and Convalescent Children, ently held at the residence of Miss Helen Gould, was announced that Mrs. Andrew Carnegie had mised to duplicate the largest donation made for benefit of that organization. Other large dona- ons were made, and it was stated that a large part the money given will be used for a tuberculosis ttage or hospital on a site not chosen in the pines d as near New York as possible.

Changes in the Medical Faculty of Columbia Col- e.—At the meeting of the Board of Trustees of olumbia University held on April 11, the announce- ent was made that Dr. William T. Bull had ten- ered his resignation as professor of surgery at the niversity, to take effect June 30, 1904. Upon the recommendation of the Medical Faculty, Dr. George E. Brewer, professor of clinical surgery, was assigned to a seat in the Faculty of Medicine. It was also announced that owing to his enforced absences from the city, the resignation of Dr. Edward L. Trudeau of Saranac Lake, N. Y., as a member of the Board of Trustees had been accepted. Dr. T. Maltack Cheeseman was elected as his successor.

Thorium Not an Element.—Dr. Charles Baskerville, Professor of Chemistry in the University of North Carolina, has just announced his discovery, that thorium, hitherto known as one of the primary elements, is complex in its nature. The professor has resolved thorium into two new elements.

Report of New York State Board of Health Commissioner.—New York State Health Commissioner Lewis, in his annual report to the Governor, says that the most prominent feature of the sanitary condition of New York State during 1903 was the epidemics of typhoid fever at Ithaca and at West Seneca near Buffalo. The deaths from preventable diseases during the year 1903 were as follows: Pulmonary tuberculosis, 13,194; diphtheria, 3,056; typhoid fever, 1,665; scarlet fever, 1,057; smallpox, 41. Total, 18,992. The chemical department made analyses of sixty-nine samples of food and fifty samples of water. Of the food twenty-two samples, or 32 per cent., were found adulterated. According to the monthly bulletins of the department, the deaths from cancer show an increase of about 500. The vital statistics of 1903 show a State death rate of 17.6 per 1,000 population and a birth rate of 21.8. The number of reports received from school principals as to the examination of the eyesight of children were small, but it is gathered from these that 14.1 of this number had defective vision.

Epidemic of Diphtheria in Montgomery.—It is reported that an epidemic of diphtheria exists in the village of Montgomery, Orange County, N. Y. The disease is said to have been prevalent for about two weeks.

The Outcome of the Controversy between the New York University and Its Former Medical Faculty.—By a recent decision of the Court of Appeals the final step has been taken toward the settlement of the controversy between the New York University and its former Medical Faculty, the members of which resigned in 1898 and founded the Cornell University Medical College. The Court of Appeals confirms the decision of the lower courts ordering the return of the building and property to the former owners. The University Medical College, like all others of its time, was originally and for many years a proprietary institution, holding its charter through the New York University but wholly independent of it in management. In the effort to improve standards of teaching it became evident that this proprietary quality should be eliminated, and the Faculty accomplished this by the aid of a gift of money from Colonel Payne, by which the ownership of the Faculty was cancelled and the property was placed in the hands of a corporation fund for this purpose, the Faculty agreeing to accept fixed salaries in lieu of a division of the profits. After a few years, with the intention of establishing a closer connection with the New York University, it was agreed that the corporation which held the property and managed the affairs of the college, composed largely of members of the Faculty, should transfer their property and function to the New York University, and that the latter should manage the college through a "Medical committee" of the Council, composed of three members who should be satisfactory to the Faculty.

On nomination of the Faculty two new members were elected to the council, and, with Colonel Payne, the donor of the money, constituted this committee. Within a few months disagreement arose over a proposed consolidation with Bellevue Hospital Medical College; the recommendations of the Medical Committee were overridden by the Council, and the Faculty held that the agreement had been broken. Reëstablishment of the original status was refused by the Council of the University, and a year later the Faculty seceded and established the Cornell University Medical College, and the Corporation which had transferred the property sued for its return. The New York University then took over the Bellevue Hospital Medical College as its medical school, with most of the Faculty, and made it its medical department. The property is valued at $150,000. The results of this final decision are that the large buildings formerly occupied by the New York University adjoining the Loomis Laboratory ars now the undisputed property of the Corporation, many of whom are members of the Faculty of the Cornell University Medical College.

The Germ of Mumps Said to Have Been Isolated.—According to some of the lay journals, a germ believed to be that of mumps has been discovered by Dr. Samuel Darling, resident pathologist of the Baltimore City Hospital. A patient in Baltimore is said to have died from mumps uncomplicated with any other disease, and an autopsy was performed on the body. Cultures were made by Dr. Darling, who eventually isolated the germ, which is described as differing from the bacillus of typhoid fever in that it is shorter, it also occurs in pairs and is thicker than the germ of tuberculosis.

Plague in India.—The deaths by bubonic plague in India during the week ended on March 19 numbered 40,527, an increase of 7,000 over those for the preceding seven days.

State Hospital Visitors.—The Governor of New York State has made the following appointments as members of the board of visitation of State Hospitals: Manhattan Hospital, George D. MacKay of New York City, reappointed; Hudson River Hospital, Reginald W. Rives of Wappinger Falls, in place of Frank B. Town, whose term of office is soon to expire; Middletown, John E. Iseman of Middletown, reappointed.

Bubonic Plague in Peru.—According to a telegram from Mr. Dudley, the United States Minister at Lima, Peru, received at the State Department, Washington, on March 31, that city has been attacked by Asiatic plague. The same telegram states that there were thirty-two cases in the week ended March 26, and that two deaths occurred on March 30. The State Department has notified the Marine Hospital and the Public Health Service of Mr. Dudley's information.

New Charity Seeks Charter.—Sisters Lariantes of Holy Cross from Le Mans, Sarthe, France, is the title of a religious charitable organization which has made application to the State Board of Charities to incorporate, for charitable work in New York City.

Physician Refuses a Bequest of $1,800,000.—Dr. William A. Harroun of Denver, Col., was recently left an inheritance which, it is reported, amounted to $1,800,000. Dr. Harroun, however, with an independence as rare as it is commendable, declines to accept the money, but has turned it over to his sister.

Telephone Girl Recovers Damages for Accident When at Duty.—For deafness of her left ear, caused by an electric shock from a telephone receiver, Miss Mary Schultz of Chicago secured on April 1 a verdict of $15,000 against the Chicago Telephone Company.

Cincinnati Board of Health.—The physicians of Cincinnati are not represented on the City Board of Health, and the vacancy left by the death of Mr. Allison has not yet been filled. Dr. C. L. Bonifield introduced a resolution at the Academy of Medicine on Monday evening which practically demands of Mayor Fleischmann that he appoint a medical man to the vacancy on the Board of Health. The Board of Public Service is an elective body, and it has been the custom of the mayor to appoint this body in toto as the Board of Health of this city. The appointment of Mr. Hutton to the Board of Public Service has not, it appears, filled the vacancy on the Board of Health, and it is this place the doctors are anxious to secure for one of their number.

Cincinnati Hospital.—At present the entire hospital is occupied by public patients, but at a meeting of the Board of Medical Advisors this week it was decided to open the pay ward in the near future. It may be possible that two wards, instead of one, may be reserved for pay patients.

Educational Applications.—The following appropriations were made by the Legislature for Ohio Educational Institutions: Miami University is given $25,000; the Ohio State University $50,000 for a new chemical building and $50,000 for building and live stock for the agricultural college. For the Ohio University at Athens $40,750 is appropriated, and $35,000 goes to Wilberforce.

Dr. S. Weir Mitchell has written a most entertaining sketch of Washington's youth, told in the form of an autobiography, the first installment of which is published in the April *Century*. The author imagines Washington sitting down at Mount Vernon in his old age and recording solely for his own eye the story of his "youthful life and the influences that affected it for good or ill." The author has so fully entered into the habit of mind of Washington that it is impossible for the ordinary reader to separate in the text the passages taken out of his actual writings from those which Dr. Mitchell imagines him to write. In the same issue is an interesting paper on "Protozoa and Disease," by Dr. Gary N. Calkins, adjunct professor of zoology at Columbia University, in which the writer discusses this comparatively new chapter of microbiology in its pathogenic relations.

Rawson Dipsomaniac Bill.—A bill introduced in the Ohio Legislature under the above title provides for the appointment of a commission, by the Governor, to serve without compensation, to investigate this subject. The second section of the bill sets forth the manner of conducting the investigation as follows: "It shall be the duty of the commission to gather from the Judges of Probate and Police Courts, Superintendents of State Hospitals for the Insane, Chiefs of Police and officers of institutions for the care of the defective and criminal classes in Ohio and other States, such data as will enable them to determine the advisability of establishing a State hospital for the treatment of habitual inebriates and dipsomaniacs and persons enslaved by morphine and cocaine. Such data shall be reported to the Governor January 1, 1906, and transmitted to the General Assembly."

Trouble for the Cincinnati Academy.—Members of the Cincinnati Literary Society may take action to prevent the Cincinnati Academy of Medicine from holding its meetings in the Literary Society Club rooms, 25 East Eighth street, in the future. Members of the literary society object to some of the methods of the Academy of Medicine.

The Alleged Improvements in Water Purification.—Dr. George I. Moore, head of the Laboratory of Plant Physiology in the Department of Agriculture, is reported to have devised an agent which will kill the germs of typhoid fever and cholera. In a statement given out by the department the following are said to be the properties of the solution as given: "The solution is absolutely fatal to typhoid in a dilution so great that it would hurt no one, and it would be impossible to find it in the water. It is tasteless and odorless, and one could drink fifty gallons of it a day without harmful effect." Aside from this it is also claimed that by its agency the malarial germ can be destroyed and malarial epidemics prevented, at the same time the mosquito is being exterminated by the destruction of its aquatic food supply.

Appropriation for Iowa State Hospital.—The Iowa Senate has voted an appropriation of $125,000 for the establishment of a State Hospital for inebriates at Knoxville. It is said that the former industrial home for the blind will be used, and new buildings erected. The bill provides that treatment is not to exceed three years The Home Committee on Appropriations has also passed a bill devoting $50,000 to the erection of a State Hospital for Consumptives.

The Kern County (Cal.) Medical Society obtained warrants, on March 24, for the arrest of two physicians in Bakersfield on the charge of having criminally procured an abortion. It is stated that five deaths have occurred in Bakersfield alone as a result of this form of malpractice, since the first of January. The Kern County Society is to be commended for its action. Other societies along the coast might well follow the example, but San Francisco is just now agitated over a common practice of the stork to deposit the young infant upon the door-step of the wrong abode.

"Health Hints for the Household" was the alliterative title of a pamphlet which the San Francisco Board of Health desired to publish, but after the manuscript had been prepared it was found to possess the dimensions of an encyclopedia, and the project was abandoned.

Examining Board.—The County Civil Service Commission (Illinois) has announced the members of the examining board for the promotive examination for the work of senior physicians at the Dunning institutions, as follows: Nervous and Mental Diseases—Drs. Sydney Kuh, Hugh T. Patrick and Daniel R. Brower. Medicine and Surgery—Drs. Frank Billings, John B. Murphy and L. E. Schmidt. Tuberculosis—Drs. W. A. Evans, Geo. W. Webster and A. C. Klebs. The examination will take place at the Dunning institutions April 14, 15, and 16.

Appointment of Consulting Staff.—The following are the appointments to the consulting staff of the Dunning (Illinois) institutions: Dr. Frank Billings, consulting physician (internal medicine); Dr. John B. Murphy, consulting surgeon; Dr. Wm. A. Evans, consulting pathologist; Dr. Hugh T. Patrick, consulting neurologist; Dr. Arnold C. Klebs, consulting physician (tuberculosis).

An Apostle of Nakedness.—San Francisco has an apostle of nakedness. He is not the forerunner o af new sect or creed, but simply an examplo of higher development along the line of health fanaticism. He expresses the intention to go to Hawaii, where he hopes to be permitted to lay aside the burdens of civilization so far as raiment is involved. This failing, he will doubtless establish a health magazine.

Microbes Sent to Farmers.—It has been reported from Washington that a patent has been issued for a process discovered by Dr. George T. Moore of the Department of Agriculture for the production of bacterial cultures employed in inoculating soils for the successful cultivation of clovers of all kinds, alfala, soy beans, cow peas, and many other similar members of the legume family. The patent is given to the people of the United States forever in effect, the object being to forestall any effort to patent such a process and by that means circumscribe the efforts of farmers to improve their soils by raising leguminous crops.

Dr. W. W. Roblee of Riverside, Cal., has been appointed a member of the Board of Pension Examining Surgeons for Riverside County.

University of Pennsylvania, Department of Medicine.—The Medical Department of the University of Pennsylvania will conduct, as usual, a summer school in medicine. It is announced that the course will begin on May 9, and extend over a period of six weeks. In most instances the individual courses will be limited to ten students.

Tuberculosis.—In an address recently delivered before the Progressive Health Club on this subject, Dr. Geo. W. Webster, President of the Illinois State Board of Health, stated that the State Board of Health had just completed a set of statistical tables which show that the number of deaths in Illinois from consumption during the year 1903 was 70,26, while pneumonia claimed nearly as many, 6,830. The greatest source of infection from this disease was through the medium of the sputum, and if the sputum of every consumptive could be destroyed, he believed the disease could be banished from the face of the earth. Experience had shown consumption to be a preventable disease, and in 70 per cent. of the cases a curable one, if taken in time. He urged that a sanatorium for the treatment of consumptives be established in every State in the Union. The stamping out of this dread disease was a matter for education and evolution. It depended upon right living, cleanliness, sunlight, temperance, good food, fresh air, and proper care.

Instruction to Railway Employees in First Aid.—All the employes of the operating department connected with the Pennsylvania System will be given first-aid instruction hereafter. The plan will be put into effect on the lines in the East and West. The plan is comprehensive, and includes equipping all baggage, mail, express, working and wrecking cars, terminals, yards, offices, shops, and important stations with stretchers. The so-called first-aid boxes will also be provided in all locomotives, terminals, yard offices, shops, and stations. These boxes will contain six sterilized first-aid packages. Each package contains one large triangular bandage, one ordinary roller bandage, two compresses, and two safety pins. No drugs or liquors will be provided. The boxes will be of wood, and will contain a tin box, in which the materials will be confined. The Pennsylvania is also perfecting plans for the instruction of several hospital cars adapted for the transportation of the sick, and to be used in emergency cases. The employees to be instructed include all passenger and freight trainmen, enginemen and firemen, and all employees at terminals, yards, and shops. The employees will be arranged in classes, and will be instructed by medical examiners connected with the Pennsylvania relief department. They will be taught how to place injured persons on stretchers, how to best transport the injured, and will be schooled in the simple means of taking care of wounds, fractures, burns, and shock, without the use of drugs or liquor. The instructions will include emergency treatment of pain, unconsciousness, convulsions, and heat prostration.

Hospital Appropriations.—The following appropriations were made by the Legislature for Ohio Hospitals: The Athens State Hospital, $164,500, of which $12,000 are for land, and $30,000 for improvements. Cleveland Hospital gets $238,000, of which $48,000 is for improvements and $13,000 for ordinary repairs. The Columbus State Hospital gets $273,000, including $30,500 for improvements. Longview Asylum gets $142,500 for current expenses. Dayton Hospital gets $276,000, of which $149,000 is for improvements. The Columbus State Hospital gets $273,940, of which $25,000 is for a railroad switch and $20,000 for boilers. The Toledo Hospital is given $250,050, most of which goes to current expenses. The Boys' Industrial School at Lancaster is given $15,000 for a hospital and $5,000 for a dairy barn, while the girls' school gets $5,000 for a heating plant. For additions to the gymnasium for the institution for the Blind $10,000 is given. The Institution for Feeble-Minded gets $15,000 for a custodial building, $15,000 for a light plant, $10,000 for sewers, $5,000 for heating and $15,000 for boilers at the custodial farm. The Sandusky Soldiers and Sailors' Home gets $85,180, including $7,000 for repairs, $1,200 for furniture and $500 for roadways. The Xenia Orphans' Home gets $16,000 for an amusement hall, and the Hospital for Epileptics at Gallipolis is given $5,000 for completing the industrial building. The sum of $25,000 is given for topographical surveys.

St. Louis Medical Society.—At a meeting of this society on March 12 three cases of situs transversus were presented. Dr. Louis H. Behrens presented the case of a man about forty years of age in whom there was a complete transposition of the heart, liver and spleen and probably of all the abdominal viscera. Dr. J. R. Clemens presented a patient, a young girl about fifteen years of age, in whom there was complete transposition of the viscera of the thorax, and Dr. Wm. C. Mardorf also presented a case, that of a girl about seven years of age. Dr. R. J. Terry showed specimens preserved from a case of situs transversus in which all the viscera were entirely transposed. All the viscera in the thorax were transposed, and in the abdomen the stomach was on the right side, the spleen on the right side, the curve of the duodenum reversed, the pancreas on the right side, and the appendix on the left side.

American Academy of Medicine.—The twenty-ninth annual meeting of the American Academy of Medicine will be held at the Shelburne, Atlantic City, beginning on Saturday, June 4, at 11 A.M., and continuing through Monday the 6th. The program includes: (1) The report of the council on the recommendation of a paper read at the last meeting by Dr. H. Bert Ellis of California, on "The Necessity for a National Bureau of Medicine and Foods." (2) The report of the committee to investigate the teaching of Hygiene in our public schools. In order that this report may be discussed intelligently, the committee will publish the laws relating to the teaching of hygiene now in force in the United States, in the bulletin of the American Academy of Medicine, to be published in April, 1904. (3) The reports on the results of the examinations before the various State Boards of Medical Examiners of 1903. (4) A symposium on the "Relation of Physicians to Dentists and Pharmacists." Several papers of value are promised for this symposium, and the subsequent general discussion will be helpful. (5) A symposium on "Are Modern School Methods in Keeping with Physiological Knowledge?" Apart from the papers promised, arrangements are being made for a discussion opening up the whole subject from various points of view. (6) In addition to the above, there will be several papers upon independent topics, affording a variety to the program. Dr. John B. Roberts of Philadelphia has selected "The Doctor's Duty to the State" as the title of his address as president. This address will be delivered on Saturday evening and the social session will be held on Monday evening. The secretary of the academy is Dr. Charles McIntire, Easton, Pa.

Milk Law Upheld.—In the Court of Criminal Correction in St. Louis four test cases against dairymen charged with violating the city milk ordinances were decided in favor of the city. The trial of the cases occupied about three days and many expert chemists were called as witnesses on both sides. The four cases are: Samuel Polumsky, fined $25 and costs for selling artificially colored cream; Jos. L. Schuler, $25 and costs for selling milk containing formaldehyde; Peter Reuter, $25 and costs for selling cream containing an insufficient amount of fat; John Heitman, $25 and costs for selling skimmed milk below the minimum amount of composition.

Obituary Notes.—Dr. ELISHA CROWELL died in Philadelphia on April 6, at the age of seventy-six years. He was a graduate of the College Department of Princeton University and of the Medical Department of the University of Pennsylvania in the class of 1851. He was a resident physician in the Philadelphia Hospital from 1851 to 1853 and physician to the Satterlee Hospital during the Civil War.

Dr. CHARLES WILLIAM NEWTON of Toledo, Ohio, died in Phoenix, Ariz., of tuberculosis, February 2, 1904, aged thirty-six years. He was a native of Marietta, Ohio, a graduate of Marietta College and of Ohio Medical College, Cincinnati. He served one year as interne at the Good Samaritan Hospital of that city and two years as assistant surgeon, National Military Home, Dayton, Ohio. Subsequently for nine years he practised his profession in Toledo, Ohio, where he was a member of the staff of Toledo Hospital and surgeon of the Toledo Naval Reserves. He afterward became First Assistant Surgeon, Tenth Reg. O. V. I. during the Spanish War, seeing service in the typhoid malaria epidemic of Camp Meade, Pa. He was a member of the Toledo Medical Association, the Ohio Pediatric Society, the Spanish War Veterans, and the Loyal Legion.

Dr. W. F. DOHRMANN, a retired physician of San Francisco, died of pneumonia at Santa Barbara on March 26, at the age of thirty-five.

Dr. A. B. ARNOLD died at San Francisco on March 28, in the eighty-fifth year of his age. He was a native of Bavaria, but received his education in this country, receiving his degree in medicine at Jefferson Medical College, Philadelphia. For several years he engaged in practice at Easton, Pa., then went to Baltimore, where he resided until his removal to San Francisco in 1898. He occupied the chair of medicine in the old Washington University, Baltimore, and later became one of the founders of the College of Physicians and Surgeons of that city, his official position being Professor of Nervous Diseases. He was twice elected President of the Maryland Medical and Surgical Association. Outside of the profession he was well known as a translator of Hebrew and Arabic.

PHILIP BISSELL, M.D., died of pneumonia at the New York Hospital on April 10, 1904. Dr. Bissell was twenty-eight years old, a graduate of Columbia University and the College of Physicians and Surgeons. He had just completed his service as interne at the New York Hospital and entered upon the practice of his profession in New York. A man of the highest promise in the career which he had chosen he had already won a large circle of devoted friends.

THE HERTER LECTURES.*

By Prof. PAUL EHRLICH,
FRANKFORT, GERMANY.
(From Our Special Correspondent.)

LECTURE I.

THE MUTUAL RELATIONS BETWEEN TOXIN AND ANTITOXIN.

President Remsen of the University introduced Professor Ehrlich to the large audience which had assembled to do him honor, in a few well-chosen words, called attention to the eminence which the distinguished visitor had attained in this interesting and important field of research.

Professor Ehrlich, by way of introduction, spoke of the importance of the practical and theoretical study of immunity in modern medicine. The influence of the side-chain theory and the relations between the constitution and distribution of chemical substances and their pharmacological action was also commented on. In dealing with the opposing views on this subject, he showed that criticism of their experimental basis often eliminated errors and reversed their significance. The utility of a succinct nomenclature and symbolic representations by means of algebraic and chemical signs formed an essential feature in the study of this subject. Characteristic diagrams, similar to those employed by Dr. T. M. Prudden, in an article in the Medical Record of February 14, 1903, greatly helped to elucidate his meanings.

The history of the side-chain theory was then traced, beginning with studies on the localization of various dyes, such as methylene blue and neutral red, and their relations to cellular chemistry. The fact that immunity may also be produced with poisonous proteids (ricin, abrin, and robrin), led to the definition of immunity not only as bacterial, but also as a general principle. The older obscure conceptions of the relations between antitoxin and toxin were briefly discussed, and it was then shown how experiments in vitro eliminated the obscurities of those in animals. Professor Ehrlich then dealt with the subject of toxoids coming back to a further discussion of the side-chain theory at a later point. It was a difficult matter to apply a purely chemical conception—for example, in the case of diphtheria toxin, for here the law of equivalence was apparently violated. Different lots of diphtheria toxin, though neutralized by a single immune unit, were found to contain different numbers of lethal doses. Investigation demonstrated that upon standing the diphtheria toxin lost toxicity, but retained undiminished its affinity for antitoxin. The toxin molecule was quantitatively transformed into a non-poisonous toxoid. This was also illustrated by the chemical analogy of anilin and sulphanilic acid. The simplest explanation of toxoid formation rested on the assumption that the toxin complex contained two groups of different functions, the first group being the haptophores, by which the complex entered into chemical unions, and the second, the toxophores, which occasioned toxic action. Behring's objections, exemplified in hydrocyanic acid, Ehrlich did not think were justified, because of the simple constitution of that poison. Complex organic compounds had repeatedly been shown to contain groups which confered definite properties upon the whole molecule. Thus he referred to the anæsthesiophore function of the benzoyl group in cocaine, which when eliminated rendered the cocaine ineffective as an anæsthetic. Of a similar nature were the functions of the chromophore and anxochrome groups in dyes—the color reactions of proteids due to definite groups (tyrosin, tryptophan, etc.). Further evidence of this complex character of toxins was also furnished by the studies of hæmolysins and bacteriolysins, which had their origin in the union of an amboceptor and complement and were analogous to toxins, the amboceptor representing the haptophore and the complement the toxophore group. Keyes studies on the lecithid of cobra-poison were also commented on in this connection.

A further consideration of the side-chain theory followed. It might be said that the conception of the complex nature of toxins and other bodies form the basis of the side-chain theory. The so-called receptors might be said to subserve normal assimilative processes which were of a synthetic character. Only those substances could be chemically incorporated or assimilated with the protoplasm which possessed a grouping most closely related to some constituent of the cell. Professor Ehrlich very aptly compared this fitting into its constitution as a key did in a lock. The toxins represented, to a certain extent, toxic foodstuffs. It was a matter of mere chance whether they encountered suitable receptors in the cells of a particular animal species or not, as was shown by the irregularity in the action of given toxins in the animal kingdom. In further elaborating the side-chain theory he claimed that the antitoxins were receptors, produced in excess, and liberated from the cells. Appearing in the fluids, they united with the toxins for which they had specific affinity, and thus protected the cells, which had receptors of similar affinity, from damage. Not only toxins, but also toxoids, called forth antibodies. It was therefore chiefly the haptophore group which caused the cell reaction, yielding antibodies by occupying the specific receptors.

The evidence in favor of these theoretical conceptions he summed up as follows: (1) The demonstration of specific receptors in organs susceptible to a particular poison. This had been shown in Wassermann's experiments on the union of tetanotoxin with cerebral tissues. (2) The demonstration by Pfeiffer that during the latent period, before the antibodies appear in the serum, they might be obtained from bone-marrow with salt solution. (3) The demonstration of the presence of receptors produced and fixed in definitely localized tissues. Other evidences were mentioned but not discussed.

The toxophore group, which was next taken up, needed not necessarily to be simple, but might comprise various constituent groups, which might be identical or different. Thus, he showed that strychnia contained two oxygenated radicals, both of which produced convulsions; and the drug owed its extraordinary toxicity to a combination of the two. Ricin probably contained two toxophore groups, one agglutinating erythrocytes, the other causing its general toxicity. Three varieties of toxoids might be obtained from ricin, one non-toxic but agglutinating, one toxic but not agglutinating, both of which were incomplete toxoids. The third, complete, was neither toxic nor agglutinating. Tetanotoxin and diphtheria toxin also appeared to contain various toxophore groups. So in diphtheria it was necessary to distinguish between complexes which occasioned acute manifestations and those which caused chronic effects. It was possible that certain partial groups acted more powerfully on certain animal species than on others, and this might explain the observations emphasized by Behring that modified toxins met with a range of susceptibility in the animal kingdom different from that of the original, unmodified toxin.

Of practical importance was the question whether, for the rapid production of the antitoxin,

*Delivered at the Johns Hopkins University, Baltimore, Md., April 12, 13, and 14.

it was more advantageous to use only toxoids, or whether the presence of partial components of the toxophore groups exerted a more favorable cell-irritation.

Professor Ehrlich next took up the subjects of receptors, susceptibility to toxins, and the relations to metabolism. The receptors of the cells were constituents of the protoplasm possessing a certain independent individuality. They acted as localizers or condensers to the toxins and might, from an infinitely dilute solution, occasion a concentration of toxins in particular cells similar to the concentration of picric acid, which took place when wool was immersed in a dilute solution of the latter. The susceptibility to toxins he divided into the following varieties: First, those marked by great susceptibility, which includes toxophilic receptors exclusively in vital organs (guinea-pig or mouse and tetanus). Second—slight susceptibility, because of wide distribution of toxophilic receptors in different tissues, *e.g.* connective, which lock the greater part of the toxins and thereby protected more important tissues (fowl or rabbit and tetanotoxin). Third—insusceptibility, though toxophilic receptors were present, because toxophore groups did not act on protoplasm. This was accompanied by an abundant production of antibodies and was a rare condition, well illustrated by the behavior of the crocodile toward tetanotoxin. Fourth—insusceptibility through lack of toxophilic receptors. Of this there were numerous examples.

Definite receptor-complexes were associated with definite forms of metabolism. Uniform metabolic processes implied uniform receptor complexes, and therefore a uniform susceptibility to toxins. Individually, however, varying functions revealed themselves in extraordinarily variable susceptibility.

The study of the receptors had been of particular importance in elucidating the processes of assimilation. Former methods applied to damaged cells were not sufficiently refined. Isolated receptors, however, obtained by immunization made an accurate study of assimilation and catabolism more approachable.

The demonstration that erythrocytes possessed extraordinarily numerous and various receptors was particularly important. It indicated that these corpuscles, in addition to their function as oxygen-carriers, played an important rôle in metabolism in storing intermediary bodies.

Investigation had been greatly aided by a knowledge of the receptors, since they could be used in the analysis of animal and vegetable poisons to separate them into partial toxins having different haptophore groups. Thus it was possible, by specific locking with specific antibodies, to analyze snake poison into neurotoxic, endotheliotoxic and two hemotoxic components. Of the latter, as determined by Meyer, Flexner, and Kyes, one agglutinated, and the other, through the formation of lecethid, hemolysed the blood.

In conclusion, Professor Ehrlich spoke of the immunization industry, which had for its aim the production of sera of highest potency and the progress which had been made. Sera of much higher toxic value than had hitherto been obtained would be the result. The knowledge that the immunity reaction was reduced by too highly toxic treatment of the animals was spreading. An effort was being made to restrict this immune reaction to tissues of slight vital importance, (*e.g.* connective) and to protect vital organs from injury. In this direction were the methods with toxin and antitoxin injected separately or after admixture.

Progress in the production of curative sera could only be expected when it became possible to obtain antitoxins of greater avidity than those now procured. Kyes had demonstrated that, through the immunization of rabbits with cobra lecethid, it was possible to obtain an antibody of considerable higher avidity than that obtained by Chalmette with cobra venom in horses. The selection of particularly favorable animal species and the use of toxins of least avidity would, most probably, bring this problem much nearer to its final solution.

Lecture II.

Physical Chemistry versus Biology in the Doctrines of Immunity.

The second lecture of the series practically resolved itself in an exposition of the biological theories advocated by Professor Ehrlich and his school in contradistinction to the physico-chemical theories as applied to the study of toxins and antitoxins, chiefly identified with the names of Arrhenius and Madsen.

Their belief is tetanolysin, *e.g.* is a uniform substance possessing only a weak affinity to its antitoxin, and that its neutralization occurs in accordance with the law of Guldberg and Waage. The views advanced by Arrhenius and Madsen met with favorable reception in certain scientific circles lacking special competence in sero-therapeutical questions. In protesting against the claims of these authors for exclusive priority, Professor Ehrlich showed that the path of biological investigation followed by them—the method of partial neutralization of toxins—was developed by himself after long years of work. He denied, moreover, that his investigations represented merely an application of Thomsen's principle in his study of affinities between strong acids and bases, for Thomsen, in distinction to himself, worked only with material substances.

The reproach that the investigations were inaccurate, and had been conducted without sufficient consideration of sources of error, he also claimed was unwarranted. The most important results had been confirmed by them, especially as regarded the existence of toxoids and their occurrence with varying degrees of avidity. Professor Ehrlich felt assured that his own and his collaborators' researches had been conducted with the utmost precision and care. He had always chosen the simplest explanations, and these, as in the case of diphtheria toxin, gave place to more complex ones only when the experimental results made this necessary.

The methods and results of partial neutralization were then discussed. It was first necessary to determine whether in the production of toxoids a change in avidity for antitoxin occurred. The method for this was by partial saturation or neutralization. A prerequisite to this was the exact determination of the test-constants, the fatal dose, etc., which referred to the immunity unit. This he described in detail. If the antitoxin were a single substance of uniform composition, and the antitoxin possessed for it a strong affinity, like that between hydrochloric acid and potassium, the quantities of toxin which disappeared or were neutralized in these mixtures would be in direct ratio to the quantities of added antitoxin. In fact, however, the process of neutralization took place differently, and it was of advantage to express these experimental results in graphic form for which two methods were available. The first, the author's method, called by him the "spectral" mode of representation, which showed, step by step, the extent of diminution in the number of toxic doses effected by a definite small quantity of antitoxin. The second was the "linear" method used by Arrhenius, in which the quantities of antitoxin added were represented on an abscissa, and those

of the active toxic doses on the ordinates. Professor Ehrlich considered this latter method objectionable, because the graphic line corresponded only in its middle part with the values actually found, and at both ends showed considerable deviation. Moreover, the construction rested on false premises.

By the spectral mode of representation it was possible to distinguish three zones: (1) pure toxid, (2) pure toxin, and (3) a mixture of equal parts of both, which he designated as hemitoxin. Pure toxoid occurred often in the form of a prototoxoid, which possessed a stronger avidity for antitoxin than all other components of the toxin. A certain quantity of antitoxin might be added to a solution containing it without lessening in the slightest degree its toxicity. The second zone in the spectrum was of relatively short extent and was characterized by the fact that one combining unit removed only a fraction of the lethal dose. The third zone he called the toxone zone. Toxone was one of the primary products of secretion of the diphtheria bacillus, possessing the same haptophore group as the toxin, but of far less avidity. In the process of partial neutralization it combined with the antitoxin. Toxone was responsible for the diphtheritic paralysis in guinea-pigs during the period between the fourteenth and thirtieth day.

The objections to these ideas advanced by the physico-chemical school were next considered. Arrhenius concluded that inasmuch as the neutralization of tetanus toxin proceeded in the same way as the neutralization of ammonia by boric acid (Danyzs), it was superfluous to assume the existence of different components and sufficient to assume a single uniform toxin with weak affinity for its antitoxin. In Ehrlich's reply he stated that at the outset of his investigations he was led to assume a strong affinity between toxin and antitoxin, and later on was able to prove it experimentally. The difference in effective strength in various specimens of toxins he believed might be referred to the presence of toxone.

What then, he asked, was the evidence advanced by Arrhenius in favor of the view that toxin and antitoxin were actually substances of weak avidity? The entire reasoning of these authors proceeded from the assumption that neutralization of toxin and antitoxin was an interchangeable or reversible reaction. If the latter could be proven false, the basis would be withdrawn from all the deductions of Arrhenius.

Von Dungern had made some experiments on this point, however, which showed that the union of diphtheria toxin and antitoxin did not proceed in accordance with the ammonia and boric acid scheme of Danyzs previously mentioned. The phenomena of combination were explicable only upon the assumption of a complex constitution of the diphtheria poison. Constituents of the diphtheria poison with weak affinity after combining with antitoxin might eventually become so firmly bound that the union could be only incompletely broken by toxin of stronger avidity. Dr. Sachs had also proven the same thing with tetanolysin.

These results afforded another argument against the views based on a linear representation of the calculated values of toxins.

Tetanolysin, on account of its tendency readily to decompose and the difficulty of conducting hæmolytic experiments with absolute accuracy, was ill adapted for precise determinations of the kind under consideration.

This substance, however, was the axis of Arrhenius' investigations, and as Ehrlich very aptly put it, neutralization experiments with this substance encountered on the one side the Scylla of incomplete union, and on the other the Charybdis of destruction of the poison.

The diphtheria curves which Madsten presented at the last congress in Brussels were next commented on. The fact that some of the figures underlying the construction of the curves were later on proven to be wrong, demonstrated that even from erroneous figures, curves in entire harmony with the theory advanced, might be constructed.

Ehrlich thought that at present there were no satisfactorily demonstrated facts to warrant the application of Arrhenius' conceptions to the diphtheria toxin. The large variations of the disassociation-constants necessitated the assumption of an extraordinary multiplicity of poisons, whereas Ehrlich's conceptions were satisfied by the acceptance of a much smaller number.

In conclusion he stated that his views furnished a far better explanation than those of Arrhenius of numerous facts in the domain of toxins, such as the process of spontaneous enfeeblement of toxins, their passage into a state of stability, the reduction of the toxone zone, the capacity of completely neutralized poisons to produce antitoxin (as lately shown by Park). He believed that what he had established by years of effort would withstand criticism and prove itself to be real and vital.

HOSPITALS AND FUNDS—DISEASES OF THE PANCREAS—SMALLPOX—A LARGE FAMILY—DR. FULLER—LONDON UNIVERSITY PROVOST TRAILL, M.D., LLD.—PROFESSOR BYERS—DEATH OF DEPUTY SURGEON-GENERAL CAYLEY.

LONDON, March 25, 1904.

THE season of annual meetings is still upon us and appeals for hospitals come in by every post. Yesterday the National Consumption and Gordon Hospitals were holding their meeting, as also was Mrs. Gladstone's Convalescent Home. The day before the Poplar Hospital, one of the most meritorious, as it is largely supported by workingmen, the North Eastern, another in a dense, poor neighborhood, and the Mount Vernon, were urging their needs on the public, as were some others during the week. And all the time numerous non-medical charities of all kinds are competing for the help of the benevolent. No wonder it is hard for many of them to get a hearing.

At the annual meeting of University College Hospital last week regret was expressed at the death of Sir John Blundell Maple, the donor of the new hospital now in course of erection, and which, it is hoped, will be ready for occupation by the end of the year. Sir John has, by his will, made provision for the completion of the building, the first estimate of £120,000 having been much exceeded. The treasurer then called attention to another munificent gift. Sir Donald Currie is devoting £100,000 to the amalgamation of the college with the University of London and partly to the hospital. To the latter about £20,000, it is thought, will accrue from this magnificent donation. A further sum of £2,500 is promised by Sir Donald's three daughters for the furnishing of the nurses' home. Notwithstanding this, the hospital will need further sums, for which it will appeal to the public.

The pathology of the pancreas has long been regarded as obscure, and its diagnosis as attended with many pitfalls. But of late considerable progress has been made in our knowledge of its diseases. It was, therefore, pleasant to hear that Mr. Mayo Robson, whose experience of it is unrivalled, would devote his Hunterian lectures at the College of Surgeons to the pathology and surgery of this organ. You will not have forgotten that in his address before the American Medical Association at Baltimore, in 1901, he ventured to express a hope or something more, that a method of diagnosis by urinary analysis was being investigated, which though then crude and imperfect, promised great things. Ever since then, that research by Dr. P. J. Cammidge and himself has been continued in the laboratory and by the bedside and in the post-mortem room. In every case that has come under Mr. Robson's care in which the pancreas was suspected, and in numerous control cases in which there was no such suspicion, the

test has been applied. By a special treatment of the patient's urine, certain crystals are obtained, the examination of which affords important indications in the majority of, if not in all, diseases of the pancreas. Further, their experience leads Messrs. Robson and Cammidge to think it possible to distinguish by this method between acute and chronic inflammation and between benign and malignant disease of the pancreas. Glycosuria does not prevent the reaction, but it is necessary first to get rid of the sugar by fermentation. Thus it may be practicable in this way to diagnose pancreatic diabetes. The control experiments led to the discovery that certain similar crystals might appear in other diseases in which marked tissue changes were going on. But differences in the form of the crystals and in their solubility, were sufficiently marked to distinguish them. We may therefore well agree with the opinion of these investigators that the time has come for this announcement to be made in order that the utility of the method may be tested by others.

Mr. Robson has operated on over one hundred cases for pancreatic disease, but of course in his earlier cases this urinary reaction had not been discovered. During 1900 the investigation began, and from that time the test has been systematically employed by him and hundreds of analyses have been made. The diagnoses have been confirmed in fifty-six cases by operation and in other cases by necropsy. In a number cases of cancer of the head of the pancreas with jaundice, the test either confirmed the clinical diagnosis or proved the presence of malignant disease in doubtful cases, and so prevented an exploratory operation which could have done no good. In a recent case six eminent medical men advised an operation, but the urine gave such a marked pancreatic reaction that Mr. Robson advised against it But the patient was so anxious to try it, and her medical advisers supported her desire, so that an exploration was made and malignant disease found. On the other hand, in several cases thought to be cancerous, the test pointed to inflammatory disease, and curative operations were performed. In simple catarrhal and interstitial pancreatitis, both with and without gallstones, the pancreatic reaction has enabled a diagnosis to be made and active treatment applied. In two cases the test appeared to fail, but the error was not in the reaction but in the reading of its full meaning. A catarrhal inflammation was present as a secondary symptom, as it often is in cancer. In acute pancreatitis, in abscess, in cirrhosis of the liver, in tumorous and various other diseases, the urinary reaction has been most helpful by affording either positive or negative evidence as to the condition.

The value of the new method will be appreciated when we consider the many difficulties with which we may be confronted, although the functions of the pancreas, both in reference to digestion and metabolism are becoming clearer, for the symptomatology of any pancreatic disease is not as certain as we might anticipate. Indeed, for various reasons, we can scarcely expect it to be. Thus the pancreas is seldom diseased without other organs participating; all the functions of the pancreas, except the glycogenic, may be taken up by another organ; a large portion may be diseased and yet the functions be carried on by the remainder; the disease may be in the pancreas and the symptoms point more decidedly to another organ.

Some more precise account of the chemical part of this research will probably interest your readers. For this I turn to the "Arris and Gale Lecture," which was delivered by Mr. P. J. Cammidge on 14th inst. Starting with the recognized view as to the fat necrosis so frequent in pancreatic disease, Mr. Cammidge looked for the resultant glycerin in the blood, and failing for want of quantity, turned to the kidney secretion. The procedure adopted—called reaction A—was this: Ten cubic centimeters of the filtrate of urine were poured into a small flask and 1 c.c of HCl added, a funnel having been placed in the neck to act as a condenser. The flash was set on a sand bath and the liquid gently boiled for ten minutes. A mixture of 5 c.c. of the filtered urine and 5 of distilled water was then poured into the flask, which is afterward cooled in running water. Excess of acid was then neutralized by slowly adding 4 grams of lead carbonate, and after standing for a few minutes to allow of the completion of the reaction, the urine was filtered through a moistened filter paper and the flask washed out with 5 c.c. of distilled water on to the filter. To the clear filtrate must next be added 2 grams of powdered sodium acetate and 0.75 gram of phenylhydrazin hydrochlorate, and the mixture boiled for three or four minutes on the sand bath. Pour the hot liquid into a test-tube and leave to cool. After a period varying with the severity of the case, from one to twenty-four hours, a flocculent yellow deposit is found, which under one-sixth objective is seen to consist of sheaves and rosettes of golden yellow crystals. Every trace of sugar must be removed before beginning, and albumin is best got rid of. The foregoing test proved of great value but not absolutely trustworthy, for the reaction was obtained in some other diseases in which active tissue changes were going on. Mr. Cammidge then devised a further test—B—and combining the two finds that in most cases a diagnosis can be made by urinary testing only. The differentiating test depends on the fact that the formation of the crystals is interfered with in pancreatitis by a preliminary treatment of the urine with mercury perchloride, but this is not the case in cancer and the other conditions which give a positive reaction. The procedure B is as follows: 20 c.c of the filtered urine mixed with half its bulk of a saturated solution of mercury perchloride, after standing a few minutes, is carefully filtered, and to 10 c.c. of the filtrate 1 of HCl is added. The mixture is boiled on a sand bath for ten minutes and then diluted with 5 c.c. of the filtrate and 10 c.c. of distilled water. After cooling, it is neutralized with 4 grams of lead carbonate, and the operation completed as in reaction A.

Further experiments showed that variations in the form of the crystals occurred as obtained from cancerous or non-malignant cases. Though these were clear to the experienced eye a more exact character was sought and found. This was the difference in the rate of solubility in dilute sulphuric acid. The time seemed to depend on the intensity of the inflammatory changes in the pancreas.

From numerous observations the practical results of Mr. Cammidge's work on these points may thus be summarized: (1) If no crystals are found by either A or B process, the pancreas is not at fault. (2) If crystals are obtained by A but not by B, active pancreatitis is present, and surgical interference generally indicated: (*a*) The crystals from A will in acute inflammation dissolve in 33 per cent. sulphuric acid in about one-half a minute. (*b*) In chronic inflammation they will take one or two minutes. (3) If crystals are found by both A and B methods, there may be—(*a*) malignant disease of the pancreas, when they will take three to five minutes to dissolve and operation is not advisable; (*b*) a damaged pancreas due to past pancreatitis when the crystals will dissolve in one to two minutes; (*c*) disease unconnected with the pancreas when they will dissolve in about one minute. In these two (*b*) and (*c*) the urgency of the symptoms and the condition of the patient must decide the question of an exploratory incision; but there is usually no great difficulty in referring the case to its origin when the clinical history is considered in connection with the reaction of the urine.

Smallpox is again causing some anxiety to our medical officers of health. At the Asylums Board on Saturday it was stated that forty-nine cases had been admitted in the last fortnight, an increase of forty over the previous fortnight in which only nine were admitted. Three patients had died and eleven had been discharged during the fortnight, sixty-six remained under treatment. The notifications numbered fifty. On the 19th three cases were discovered in three different wards of the London Hospital and were promptly removed to the Asylum Board Hospital Ships. The M. O. H. of the District, Dr. Thomas has given every assistance, and he seems to have traced the origin of the disease to the family of the first patient observed and to have sent some of them to the isolation ships.

A circumstantial story of a family of thirty-nine children of the same father and same mother has been reprinted by Mr. Grazebrook from "Miscellaneous Geneological et Heraldica." The youngest of the family was Thomas Greenhill, chirurgeon of London, who petitioned the Earl Marshall in 1698 to be allowed to commemorate the fact on his coat of arms. The chirurgeon seems to have attended the Earl Marshall (Duke of Norfolk), and his father had been secretary to the Duke of Albemarle. The petition was readily granted and the significant coat of arms authorized. Only seven of the thirty-nine were alive in 1698. Of the family it is said thirty-two were daughters. Thomas Greenhill wrote a work on embalming.

The King has conferred the Victorian Order on Dr. H. R. Fuller, the personal physician of the late Duke of Cambridge.

The London University has come in for another munificent gift. The Goldsmith's Company has presented it with the institute which it had carried on since 1888 for scientific and technical education, together with the buildings, equipment, and apparatus and the site of about seven acres. The company had previously presented the valuable economic library collected during many years by Professor Foxwell. The University has decided to publish the lectures delivered in its laboratory during the last two years. The first volume is out "On the Signs of Life," by Dr. Waller.

Owing to the death of the Duke of Cambridge, the Centenary Festival of the Ophthalmic Hospital (old Moorfields) has been postponed until May.

The new Provost of Trinity College, Dublin, is Anthony raill, M.D., LL.D. Though he never practised, he is herefore a member of the profession. Needless to say is great scientific position makes him one of the most minent Trinity Fellows.

Professor Byers was presented on the 18th with his ortrait, which was accepted by Queen's College, Belfast, nd a replica was at the same time presented to his wife.

Deputy Surgeon-General Henry Cayley, C.M.G., I.M.S., honorary Surgeon to the King, died on Saturday in his wentieth year. He took his M.R.C.S. in 1855 and R.C.S., in 1886, having meantime served with distinction India, where he did good work in the mutiny. He was one time Professor of Military Medicine at Netley. hough he retired in 1887, he again placed his service at he disposal of his country on the outbreak of the late ar and served with the Scottish National Hospital in uth Africa. He was given C.M.G. in 1900 and the next ar appointed Honorary Surgeon to His Majesty. He as an associate of King's College, his Alma Mater, and a ellow of Calcutta University.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

MANILA, February 10, 1904.

SAD accident lately occurred in Tayabas Province, by hich Dr. F. H. Tetamore, Contract Surgeon U. S. Army, d Dr. J. H. Williams, Medical Inspector, Board of alth, together with two American school teachers, lost ir lives. Both the above named physicians were co-erating in the suppression of smallpox which had broken t in epidemic form in that province. They were crossing Bay of Limon in a native boat when a storm came up d the boat capsized. Dr. Tetamore sank immediately, Dr. Williams managed to cling to the boat for four rs, when he lost his hold from exhaustion. Dr. Teta-re was formerly a surgeon of volunteers, accepting a ition as contract surgeon on the muster out of the unteer forces. He was one of the oldest and most pected physicians connected with the Army here, and oved by all who knew him. Dr. Williams had for some e been resident physician in the Civil Hospital in nila, and had been promoted to a higher position under Board of Health only a few weeks before his death. was a young man of much ability and pleasing person-ty and leaves many friends to mourn his untimely end.

The veterinary surgeons of the Board of Health have ently been organized into a graded corps, operating der a subdivision of the office of the Board of Health. retofore a large number of veterinary surgeons have n employed on a temporary basis in connection with ventive inoculation against rinderpest, the suppression animal diseases, the purchase and care of carabao im-rted by the Government, and the examination of ani-ls arriving at the various ports. There was, until lately, certain tenure of office or opportunity of advancement, d under such conditions the incentives to the highest ree of efficiency were largely absent. Under the new n the Chief Veterinary Surgeon will be responsible for conduct of all matters relating to the practice of erinary medicine and surgery throughout the islands, ll directly control the movements of the *personnel* under division, and maintain the necessary records.

Dr. J. M. Swan, medical missionary in Canton for twenty rs, in charge of an undenominational hospital for inese in that city, has lately been in Manila for the rpose of examining the hospitals and investigating the rk done along sanitary lines. He is reported as being ch impressed by the good work done by the Americans e in a medical and sanitary way. Dr. Swan reports Cantonese as rapidly having their primitive ideas of dicine and sanitation greatly modified by contact with ites, and as being much impressed with the value of entific medical treatment, his hospital constantly be-ming more and more popular. The first supply of pure ter in Canton was secured last year for his hospital means of driven wells operated by a windmill. A few rs ago this windmill would have been destroyed as ing an offence to the "feng shui" or earth spirits, but Chinese have now reached a point where they prefer od water to a possible injury to the feelings of the eng shui."

Among the fifty prominent Filipinos who are to be sent the St. Louis Exposition and tour the United States the expense of the Philippine Government, are Dr. rdo de Tavera, member of the Philippine Commission, r. Manuel Gomez, Secretary of the Board of Health, d Drs. Bantista Lin and Jose Albert, prominent physi-ans of Manila. The gentlemen will carry with them ll credentials, and in addition to the general sight-seeing d educational influence of travel, will particularly devote emselves to the investigation of medical matters and methods as carried out in the United States. Much good will unquestionably result from the trip, in a practical as well as political sense. Even the best class of Filipinos have but a hazy idea of America and the Americans, and this very ignorance of American strength, ideals and methods, is responsible for the native opposition, active and passive, which seems to exist about everything here which is advocated by a white man. To the medical members of the party the trip will be of immense practical value, as such medical knowledge as existed in the islands prior to American control filtered in through Spain, where the highest type of scientific medicine can scarcely be said to exist. The single medical school in the islands, from which practically all the Filipino physicians have graduated, is an institution distinctly inferior even to the second-rate American medical schools in equipment, clinical facilities, and teaching staff. As to hospitals, prior to the American occupation, the two civil and military hospitals in Manila were the only two such institutions in the islands, and even at the present time the hospital facilities where sick natives can receive treatment are far from satisfactory. It is thought that after the inspection of a few hospitals and medical institutions of learning in the United States, the above physicians will have an entirely different conception of the best way to meet the medical needs of the Philippine Islands, and will be in a position to intelligently direct the efforts of the Filipino medical men to that end. A per diem of $10 for expenses will be allowed for each member of the above party, except in the case of those in Government service, who receive a per diem of $7 in addition to their regular salaries.

One of the Filipino students sent to the United States to be educated at Government expense about a year ago, was lately returned to the islands by reason of the development of leprosy. The disease had made rapid progress, and his condition on arrival in the islands is said to have been bad. He was sent to the leper hospital at Cebu, located near his home.

Every now and then the quarantine officers detect cases of leprosy on outgoing boats, which is not strange in view of the general diffusion of this disease over the archipelago, but the above case was apparently not sufficiently developed for detection at the time of departure. Lately a Filipino woman, the wife of an American official, was removed for leprosy from a steamer on which she was about to leave for the United States, and is now in San Lazaro hospital. Another prominent American official of the Civil Government, who had married a Filipino woman, lately placed her in San Lazaro for leprosy, when he found two brothers and a sister who had been reported to him by the family as having died in Manila from other causes. As there are young children to be considered in both cases, the feelings of the unfortunate husbands and fathers can be imagined, tied to leprous wives and with the possibility of their offspring becoming leprous. A number of Americans have married Filipino wives, among them two well-known physicians, formerly surgeons in the volunteer army, and it is evident from the above that the "benevolent assimilation" of the Filipinos by this means is not without its sanitary dangers. Intermarriage with natives was looked upon with favor rather than otherwise during the Spanish administration, and the Spanish soldiers were officially encouraged to contract such marriages, but the American has a much more pronounced opposition to any admixture of the races, and such intermarriage is strongly disapproved of by American society here. Many lower-class Americans have, however, entered into more or less permanent relations with native women, and have thus been brought under the conditions and customs of native modes of life. As a result, they have been disproportionately exposed to infectious diseases, especially cholera, smallpox, and dysentery, and the far higher death rate among them, as compared with that among other Americans, is the sanitary penalty imposed for their irregularities of life. During the cholera epidemic it was particularly noteworthy that the proportion of cases occurring among those associating with native women was especially high. The ordinarily insanitary habits of the natives determine the high mortality among them, and the white race under similar modes of life succumbs even more readily, as in respect to dysentery and smallpox at least, the native manifests a relatively greater insusceptibility and vital resistance. The unfavorable effect of close association with natives has also been very apparent in the case of American school teachers, a proportionately large number of whom have fallen victims to the diseases above named. This class is scattered all over the islands, many being in small towns where it is impossible to preserve American standards of living, and from close association for many hours daily with pupils drawn from a large number of insanitary native houses it is hard to see how they could escape contact with any existing infection. In their domestic life, also, the health of many of them is

at the mercy of ignorant and indifferent native cooks and servants. The position of such teachers and other officials in small native towns is also unfortunate, in that they are frequently unable, through existing circumstances, to have the benefit of sanitary advice, or in the case of sickness to secure prompt medical treatment by a competent physician. All in all, where an American comes in close relation with the native, either through inclination or circumstance, his expectation of life must be regarded as distinctly lowered over that unavoidably connected with exposure to tropical climatic conditions unfavorable to the white race.

In this connection, the recent extension of the period of tropical service, by the War Department, for officers serving in the Philippines, is not at all approved by the army surgeons in the islands. There is no question but that such extended service in the tropics has a debilitating effect upon the white man, and to a greater extent upon the white woman. There are a few notable exceptions to this general rule, and these are too apt to be pointed out as an argument for long tropical service, while the far greater number of persons leaving the islands in broken health is overlooked. The better class of Americans appreciate that unceasing sanitary vigilance is the price of health, and use their best endeavors accordingly, but even the classes with knowledge and financial means do not entirely escape, as is shown by the fact that four out of five of the American members of the commission have been attacked with dysentery within about eighteen months. The military authorities give much attention to sanitation, but conditions of service are such that officers and men cannot be at all times efficiently safeguarded. The death rate in Manila among Americans is probably no higher than that among similar classes in the average city of the United States. This, however, does not mean that conditions in Manila are as favorable to the white race as in the United States, for they are not. Climatic disadvantage and local unsanitation are, however, counterbalanced by the greater attention paid to personal hygiene by the American population, as a whole, which has learned that the use of boiled water, proper diet, avoidance of over-exertion, and sundry other matters are the price of health.

IODIDE OF POTASSIUM IN DIABETES MELLITUS.

To the Editor of the Medical Record:

Sir: It is gratifying to learn that iodide of potassium is giving good and lasting results in lobar pneumonia, as recorded in a late issue of the Medical Record, and it is hoped the profession will give the drug a fair trial in this disease.

May we not have in this powerful alterative and absorbent a remedy ranking high in the list of our remedial agents?

If iodide of potassium is not a specific in the treatment of diabetes mellitus, it certainly is a most satisfactory remedy in the treatment of this disease, giving results that are lasting.

This short communication is written for the purpose of calling medical attention to the permanent results thus far obtained by the continuous administration of this remedy to diabetic sufferers.

Writers agree as to the gravity of diabetes mellitus and its rapid tendency toward a fatal termination, and rely more upon a rigid non-nutritious diet than upon remedial measures.

Iodide of potassium has been *the* remedy given to every patient suffering from diabetes coming under my own care and that of my brother (Dr. W. A. Galloway) for the past seven years, and in every case the sufferer has been relieved and restored to health with no relapses to date.

The treatment is as follows, viz.: Give 10 to 15 grs. of iodide potassium in aqueous solution every three or four hours, masking the pungent taste with a small amount of saccharine. Continue until sugar disappears from the urine and the sp. gr. is normal, then stop administering the iodide of potassium for a few days, or until sugar reappears, when it must be again administered, but in smaller doses. Continue these intervals until sugar ceases to appear. Iodism does not make its appearance until sugar has disappeared from the urine. *Diet* is most important and *no* material restriction is placed upon it. It should be both generous and of great variety. Beef, pork, mutton, fowl, fish and game, vegetables of all kinds, melons in season *ad lib.*, coffee and tea in limited quantities, milk and water in abundance, to supply the system with fluids. Alcohol, vineous, and malt beverages would better be prohibited, together with sugar, upon general principles.

Diabetes mellitus, like fever, should be *fed* to overcome the great drain upon the system made by it.

Iodide of potassium begets a good appetite and a better digestion and assimilation, as a rule, and diabetic patients thrive upon it.

Iodide of potassium, more than any other, is a remedy that can be relied upon in the treatment of diabetes mellitus.

C. M. Galloway, M.D.

Xenia, Ohio, April 7.

Progress of Medical Science.

The Boston Medical and Surgical Journal, March 31, 1904.

Ligation of the Lacrymal Canal to Prevent Infection Following Cataract Extraction.—Alex. Quackenboss declares that infection through the tear duct is one of the common causes of suppuration following cataract extraction. Various measures have been employed to obviate this difficulty, in cases in which disease of the tear passage exists, viz., probing, syringing out the sac, treating the nasal cavity, packing the sac with antiseptic ointment, obliteration of the sac or canal with the cautery and extirpation of the sac. The first three measures entail a long course of treatment and are often ineffectual. Cauterizing the duct or sac has occasionally been followed by infection. Removal of the sac is undoubtedly the safest procedure. It must be remembered, however, that in cataract operations a great many of this class of patients are old and infirm. The writer has tied the canal, and this measure has been successful in preventing infection. He sees no reason to keep stitches in, after the corneal wound has healed firmly, and in one case he removed them at the end of the ninth day. The usual preparations for cataract extraction are made. In the case reported there was present a mucocele. Its contents were squeezed out, the eye washed out with corrosive (1-5000), then a small probe was inserted into the upper puncta, and a suture passed round the canal from the inside of the lid out. This was repeated on the lower lid. The sutures were passed 2 or 3 mm. from the puncta and were tied quite firmly. Inserting a probe into the puncta aids in controlling the lid and in placing the stitches—especially in case of the upper lid. This method is very simple, is free of pain, and can be done at the time of operation, and can be used even in doubtful cases.

Journal of the American Medical Association, April 9, 1904.

Tropical Cutaneous Myiasis in Man.—J. L. Adams, Jr., records certain observations made on the Panama Isthmus with reference to a condition likely to be of great interest in view of the proposed canal construction. He finds the most common cause to be the Dermatobia noxialis. Man and dog are hosts by preference. The Dermatobia noxialis, though not confining its attacks to man alone, cannot be called an occasional parasite of man, as it attacks those who are properly exposed. White-skinned races are more susceptible to the disease than the darker races. The period of incubation is from sixteen to twenty-three days from exposure to the development of the first symptoms. Larvæ differ in shape according to anatomic location. Grub or larva, if left alone, will not produce injurious results. Abscess and ulceration are the results of attempted expulsion without proper preliminary treatment.

Some Toxicogenic Germs Found in Drinking Water.—V. C. Vaughan thus summarizes some of his recent work in the analysis of specimens of drinking water sent to the laboratory of the University of Michigan for a period of somewhat over five years: (1) Of 709 samples, 213, or 30 per cent., contained toxicogenic germs. (2) Ten samples or 1.4 per cent., contained no bacteria capable of growth at 38 C. Of these 10 samples, 4 were from deep springs and 6 from the Great Lakes—4 from Lake Superior and 2 from Lake Huron. (3) Waters that contain no germs capable of growth at 38° C. or higher cannot cause disease. (4) Waters that contain no toxicogenic germs are not condemned. (5) Waters that contain as their only toxicogenic organism a typical colon bacillus are not condemned. By a typical colon bacillus he means one which is non-motile, produces indol abundantly, produces acid in milk, coagulates milk within twenty-four hours, and evolves more or less gas from glucose and lactose cultures. (6) Waters which contain as their only toxicogenic organism a typical proteus bacillus are not condemned. It must be remembered that other germs cannot be excluded until after repeated plating of the cultures made from the heart's blood fails to show their presence. (7) Waters that contain any member of the venenosus group or any such germ as we have marked doubtful in the table given, are condemned. (8) He has never found in drinking water a germ that responded to the Widal test.

Medical News, April 9, 1904.

Pathological Changes in Tissue under the Influence of the X-ray.—William S. Newcomet declares that it would be impossible to review and discuss in detail all of the different phases of this subject, but it can be said that no single form of degeneration is alone characteristic to the

r-ray, and the form of degeneration observed depends ntirely upon the tissue exposed and the method of *x*-ray pplication. It would seem that the effect of the *x*-ray ies upon the cell elements in the exposed parts, but why certain normal cells, such as those in hair follicles, etc., should be more susceptible than other tissue is still a question of doubt, but in lieu of the vascular disturbance found by many observers it might be thought that this cause plays an active part. Many authors speak of a thickening of the vessels. Sequeira states that two definite effects from the *x*-rays are observed by microscopical examination—a destruction of the epithelial cell, the nucleus and protoplasm undergoing lysis, and in some cells a fatty change, and a stimulation of the connective tissue elements causing the formation of healthy scar tissue.

The Early Diagnosis of General Paresis.—William A. White says that the diagnosis of paresis does not rest primarily upon the mental symptoms. Paresis is a gross organic disease of the brain, and its diagnosis must rest in the main upon an appreciation of the physical signs which these changes bring about, particularly in the field of motor disturbances. Grandiose delusions are not a necessary part of the disease. Of the oculomotor phenomena the pupillary abnormalities are most important. The loss of the light reflex with retention of the reaction to accommodation, the Argyll-Robertson pupil, is one of the most valuable diagnostic signs of beginning paresis, in the absence of tabes. A sluggish reaction to light is also sometimes found. It is claimed that a still earlier symptom is the loss of the sympathetic reflex. Of the tendon reflexes, the only one that need be considered is the knee-joint. This may be normal, exaggerated, diminished, or lost on one or both sides. The exaggerated reflex is most common. The absence of the knee-jerk is of much greater diagnostic importance. In very early stages, the especial speech defects are often hard to make out. Paretic seizures occur occasionally early in the course of the disease. Transient palsies also must be noted. Optic nerve atrophy is important, but although it is often of early onset, it is usually overlooked.

Tuberculosis of the Spinal Cord; with Reports of Cases of Tuberculous Myelitis and of Tuberculous Pachymeningitis.—Charles L. Dana and J. Ramsay Hunt, state that tuberculosis of the spinal cord occurs in five different ways: (1) As part of a general disseminated tuberculosis; (2) as part of tuberculous cerebrospinal meningitis; (3) as tuberculous tumor; (4) as a tuberculous softening or myelitis: (5) as extradural tuberculosis or tuberculous pachymeningitis with necrosis and œdema of the spinal cord. The writers report two cases. The second patient was a negro man aged twenty-four years. The interesting points of the case are summed up as follows: The acute onset after exposure to cold; the three months' duration of lancinating pains without other symptoms referable to the spine or nervous system, which, in view of the histological examination, were caused by infiltration and compression of the posterior roots; the very acute onset of the paralysis; the dissociated anæsthesia with complete paralysis of motion which suggested the existence of a central lesion of the cord. The upper and lower extremities were quite flaccid. The tactile and deep sensibility were well preserved throughout. The diminution of the knee-jerks, at first followed by great exaggeration, spasticity and clonus, was probably caused by the shock of the acute onset. The spinal cord nerve fibers showed swelling of myelin sheath and absent or swollen axis cylinders. Often the fiber was entirely gone, leaving only a vacuole. The dissociation of sensation is not explained by any distinct focus of central softening. The lesion of the cord substance seemed most marked in the lateral columns and in the neighborhood of the posterior roots. This latter disturbance would not explain, however, the sensory disturbance in the lower limbs, and it must be inferred that the necrosis œdema, by affecting partly the posterior columns, and partly the ascending (Gower's) tract of the lateral columns, was the cause of this peculiar clinical symptom. The very distinct degeneration of Gower's tracts easily followed as far as the level of the corpora quadrigemina would tend to confirm the view that it is along these tracts that pain, temperature, and sense impulses are carried. No ascending degeneration was to be found in the inferior cerebellar peduncles, and no tracts were seen running in the formatio reticularis.

New York Medical Journal, April 9, 1904.

The Wiring of Bone for Recent and Ununited Fracture, with Report of Cases.—S. L. McCurdy advises the leaving of bones down in their normal position (while they are being wired) so as to preserve their nutrition. When the end of a bone is poked out through the wound during sawing, drilling, and insertion of the wires, here must necessarily follow much damage to the periosteum; the muscle and fascial attachments are torn away for some distance and damaged further back; and when the bone is returned into the wound and adjusted, union is less likely to take place, and necrosis of the ends that have been wired quite frequently follows. He gives the details of his method, adding several illustrations. He advises the use of iron instead of silver wire, and the anchorage of bone fragments to external bridgework to hold them in position during repair. He describes and figures an instrument for cutting the ends of bones.

Guides to the Prognosis in Epilepsy, with Remarks on the Curability of the Disease; Including Reports of Thirty-four Cases.—The conclusions of W. P. Spratling are as follows; they are based on fourteen years' experience and the care of 1,800 cases: (1) Epilepsy is curable in from 5 per cent. to 10 per cent. of all cases. (2) It requires, as a rule, a long continued course of treatment—never less than two to three years—carefully mapped out and executed to the letter, not only along one, but along many lines, to effect a cure. (3) The failure to secure better results, generally, in the treatment of this disease must frequently be laid to the failure to treat the individual and his disease as a unit, and to treat them both along the very broad, comprehensive, and unyielding lines they both require. (4) The drug treatment of epilepsy alone, while invaluable in many cases and of some use in every case, often fails completely to meet the most important requirements. (5) Guides to the prognosis in epilepsy are always uncertain and unsatisfactory until treatment has been in operation from six to nine months, and in some cases a year or longer.

Skiagraphic Errors: Their Causes, Dangers, and Prevention.—In a comprehensive paper L. G. Cole notes that the field of usefulness of the *x*-rays in fractures and bony deformities is to be considered from two standpoints. First, in doubtful cases, especially cases presenting an injury near a joint, we are to determine the existence and site of a fracture. Often small fragments are chipped off the articular surface of the bones, and they are not allowed to unite, because the part is not put at rest. Afterward they set up a synovitis that is hard to treat. If we are sure of a fracture, it is far less necessary to have a single skiagraph made to show that fracture than it would be to have a skiagraph made of a part which we have often diagnosticated simply as contusion or sprain, because many times these contusions or sprains prove to be fractures of small fragments from the articular surface of the bones. To show these fractures it may be necessary to move the tube, plate, and limb in several different positions before we can detect the fracture, but a skiagraph so taken must not be interpreted as representing the relative positions of the fragments. Second, we must determine the existence and nature of any existing deformity. A skiagraph taken any time after the injury will show the resulting position of the parts. One taken within say three weeks is worthless as to showing permanent injury, because up to that time the fragments are freely movable. Finally it is advisable in every doubtful case to make a skiagraph of the sound side for purposes of comparison.

American Medicine, April 5, 1904.

Corneal Ulceration Due to Nasal Infection.—S. Lewis Ziegler says that disease is transmitted from the nose to the eye by the lacrymonasal duct, by the blood and lymph streams, and by reflex action through the nervous system. Corneal ulcer is a purely local inflammatory process, arising chiefly from infection by septic lacrymonasal secretions, and often complicated by lowered oxidation and metabolism. The writer concludes that: "The nose should have antiseptic irrigation and local treatment applied. (2) The lacrymonasal duct should be disinfected, or dilated. (3) The eye should have a soothing lotion, a mydriatic instilled, and a cauterant applied to the ulcer, if necessary. (4) The diet should be regulated tonic and antiphlogistic treatment given, and the hygiene generally improved.

The Non-operative Relief of Eyestrain for the Possible Cure of Epilepsy as Tested in Sixty-eight Cases at the Craig Colony.—William P. Spratling presents the following summary: Two mistakes were made in conducting the experiment: (1) Young patients, and those only with less injured nervous systems should have been chosen. (2) Resident or frequently visiting opticians and oculists should have been insured to make the retestings, readjustments, etc., most necessary. Despite these faults, together with incomplete statistics, etc., 19 out of 57 patients, for the only comparable terms given of three months, showed a reduction of the number of seizures of

382 (44 per cent.), and 1 in 57 was cured against 1 in 80 by all other methods of treatment that have been tried at the colony. The writer believes, judging from the result of the experiment at Craig Colony, that the permanent residence at such institutions of an expert ophthalmologist would result in great monetary saving on the part of the State. Spectacles would certainly lessen the special disease, and the number of seizures. Even if they would not do so, they would tremendously lessen headache, digestional troubles, etc. For mere humanity's sake they should be ordered. The habit of depreciation and ignoring the eyestrain factor is both cruel and unscientific.

Nervous Complications of Typhoid Fever.—Herbert A. Black states that from early record this fever has been recognized as having associated with it distinct nerve lesions. The pathologic findings which have been recorded appear to establish the fact that nervous symptoms may be due either to the toxin or the typhoid bacilli, while the pathologic changes in the nerve tissues are more often due to the direct action of the bacilli. No one symptom is more commonly present in typhoid fever than headache. Convulsions are a rare complication of the disease. They may be due to the action of the toxins upon the exhausted nerve centers, they may follow thrombosis of the veins, or cerebral arteries, or they may be due to nephritis. Delirium is one of the most frequent symptoms of typhoid fever. It may exist before any elevation of temperature occurs. Usually the more active the delirium, the more grave the danger. The diagnosis of meningitis in a disease so constantly characterized by functional cerebral derangement is complicated with much to confuse the attending physician. While the records of this complication are few, yet its existence is proved, and every case with cerebral symptoms should be carefully watched for its possible occurrence. Cerebral abscess following typhoid fever has been noted. Hemiplegia and aphasia are rare complications of typhoid fever. Neuritis occurs in a small number of cases. The most common form is probably that known as "tender toes." Paralysis in many forms is met during or after an attack of typhoid fever. Other sequelæ sometimes seen are, "typhoid spine," and insanity. There is hardly a nerve symptom which may not be present with, or follow an attack of typhoid fever.

The Lancet, April 2, 1904.

A New Method of Testing the Blood and the Urine.—The method is explained by A. E. Wright and J. N. Kilner. It is based on the following principle: A standard quantity of normal red corpuscles suspended in a measured volume of salt solution of a standard strength furnishes a test fluid. The urine, or, as the case may be, the blood fluid (serum) from which that urine is derived, is mixed in progressive dilutions in a capillary tube with measured volumes of the standard suspension of red blood corpuscles. The point is determined at which the urine or serum has been so far diluted as to allow of complete hæmolysis of the standard suspension of red corpuscles. From these data, taken in association with the data obtained on diluting the suspension of corpuscles with progressive dilutions of a decinormal sodium chloride solution, the concentration of the serum and urine is calculated. The quotient obtained by dividing the latter by the former is denoted "*the excretory quotient.*"

Pancreatic Calculi.—In the third Hunterian lecture on the pathology and surgery of certain pancreatic diseases, A. W. Mayo Robson discusses the topic of calculi formed in the pancreas, noting that they contain lime in the form of either carbonate or phosphate, rarely the oxalate. In the urine of patients with chronic pancreatitis oxalate of lime has been found in 40 per cent. of the cases. In jaundiced cases in which the bile acids take up the lime salts, this percentage has fallen to 6. The bearing of this fact on the composition of pancreatic concretions is interesting, as the normal pancreatic juice contains no calcium carbonate. As a result of their chemistry, pancreatic calculi are opaque to the *x*-rays, and hence are visible in a skiagram, which is not the case with gallstones. In color pancreatic calculi are pale and may be white. If they get into the common bile duct they receive a coating of cholesterine and may be so stained with bile as to resemble gallstones. Symptoms include glycosuria, epigastric pain radiating toward the inferior angle of the left scapula, vomiting, flatulent dyspepsia, and liporrhœa, while the urine gives the customary pancreatic reaction. An accompanying cyst, abscess, or other pathological condition may cause variations in symptomatology. Medical treatment is useless and surgical intervention is called for when once the diagnosis is established.

Corset Cancer.—R. C. Lucas discusses the general origin and spread of cancer and gives the histories of two cases. The main points of the paper are summarized in the following propositions: (1) He has attempted to demonstrate a site of cancer dependent upon the friction of the upper edge of a corset where it crosses the anterior fold of the axilla. To this he attaches no theory save that of chronic irritation, but supposing cancer to be due to an organism introduced from without, the rubbing in of such organism at this spot might aptly be compared to the rubbing in of staphylococci on the back of the neck by the collar in the production of boils and carbuncles. (2) Allusion is next made to other recognized sites of origin associated with irritation, and especially to the points of junction of mucous membrane with skin. (3) He then attempts to show how syphilis, producing injurious effects in numerous situations, often proves to be the forerunner of cancer. (4) Next inoculation and contagion are considered; the proved inoculability of cancer in animals of the same species; the self-inoculation in the human subject of parts in contact but not continuous; and the probable communication of the disease in certain cases from wife to husband. (5) The infection of cancer is next spoken of, and his original observation of three persons having cancer at the same time in the same house, published in 1887, is quoted. (6) The recent observations of various authorities as to the resemblance of the mitotic changes of cancer cells to those normal in the reproductive cells of plants and animals are alluded to as of great interest, showing why in both cancers and sarcomata there exists such an immense power of multiplication of cells, but why the cells assume this heterotype mitosis still remains to be demonstrated.

British Medical Journal, March 26, 1904.

Treatment of Puerperal Eclampsia by a Combined Method.—John Lithgow reports the case of a girl of nineteen and one-half years, who had sixty-nine severe seizures altogether. The fits appeared before labor had commenced. The writer pressed a piece of lint saturated with cocaine through the os. The patient was put under chloroform and the child was taken away. The seizures continued. The patient was then bled from a vein in the arm. After this over two pints of normal saline solution were injected into the cellular tissue underneath the breast. The patient remained unconscious for two days, ultimately making a good recovery, however. The urine contained albumin, and gave 9 gr. of urea to the ounce. The blood serum contained 2½ gr. of urea in the ounce.

A Warning Sign of Danger to the Child During Labor.—Fred. E. Daniel calls attention to the fact that in certain cases the child gasps for air in utero. This is caused by the suspension of the supply of aerated blood. This characteristic movement of the child can be felt by the operator through the handles of the forceps. The first efforts of respiration are double or duplicated—that is, they are repeated twice in quick succession. This movement is sudden and spasmodic. If immediate delivery is impracticable, the movement is repeated, strongly at first and with short intervals, which gradually become longer and the movement weaker till the child dies. The main indication is to deliver as speedily as possible, even at the risk of a moderate amount of perineal rupture, though the writer prefers to sacrifice the child to producing a very extensive rupture. At the worst, there is always the opportunity of preparing the patient's friends for the disappointment involved in the baby being born dead.

Deutsche medizinische Wochenschrift, March 24, 1904.

The Value of the X-rays in Determining the Position and Boundaries of the Heart.—Grummach describes an apparatus intended for making accurate determinations of the cardiac boundaries by means of the *x*-rays, and gives the results of a series of determinations undertaken for the purpose of comparing the efficiency of the relative and absolute dulness and of the friction method in establishing the size of the heart. It was found that the dimensions obtained from the relative dulness very closely corresponded to those found by the skiascopic method, though the latter was more accurate, while the absolute dulness gave very unreliable results. The friction method is unreliable and should be abandoned. Comparative observations on patients treated according to different plans showed that hydrotherapy was not as satisfactory in many cases as is generally supposed, and that patients with derangements of compensation could be more effectually treated by a combination of hydrotherapy with the cardiac drugs than by the former alone, as is now frequently advised.

Ultramicroscopic Investigations of the Cause of Sympathetic Ophthalmia.—Raehlmann describes observations he was enabled to make on the aqueous humor of a freshly enucleated human eye by means of the ultramicroscope. The exact nature of sympathetic ophthalmia and the manner of transmission of the infection is still somewhat doubtful, but the author believes that his investigation

proves that the process is due to bacterial invasion of the sound eye through ultramicroscopic forms of organisms which are able to pass freely through the vessel walls in any direction. In this case the enucleation was done three weeks after a perforating wound in order to save the other eye, which appeared to be in danger. Under a magnification of 2400 diameters the aqueous humor was seen to be swarming with actively motile bacteria of several types, and it is the author's view that the smaller of these, which are so minute as to be invisible to the ordinary powers of the microscope, are undeveloped forms which carry the infection through the tissue channels to the sound eye. The aqueous humor having a composition peculiar to itself is perhaps the only body fluid which forms a suitable culture medium for these particular organisms, and therefore it is the sound eye which is attacked by the sympathetic infection.

Radium Rays and Their Action on the Normal and Blind Eye.—Greeff reports the result of his official investigation of the optical properties of radium, particularly in respect to the somewhat sensational article entitled "Hope for the Blind," published by London of St. Petersburg. It is perfectly true that radium gives off rays in the dark which are visible to the human eye, but it is necessary to recognize that these rays are of two kinds. In the first place, a species of fluorescence is excited in certain bodies, which then give off indirectly rays of *ordinary* light; and in the second place, the radium itself throws off peculiar visible emanations called radium rays. Many objects, such as paper, can be excited to the fluorescent state, notably screens coated with platino-cyanate of barium, but it is easily demonstrated that the rays so given off are merely those of ordinary light, as they are obstructed by opaque bodies and throw shadows. In other words, the effect is similar to that produced by placing a lamp or candle behind a screen, and the marvelous feature consists in the fact that radium can continue to serve as source for the light indefinitely without appreciable loss of substance. The true radium rays can be detected by holding the substance a short distance away from the eye after the retina has become habituated to the dark chamber. When the radium is at a distance of about 30 cm. from the eye a peculiar diffuse, sea green radiance suddenly becomes visible, increasing as the eye is approached and diminishing with greater distance from the substance. It is impossible to determine the direction of the rays, as they penetrate all structures and give the same effect if the radium is held at the side of the head as in front. It has been the view of some observers that this effect is the result of fluorescence induced in portions of the eye itself, which thus are excited to throw off ordinary light rays; but this the author denies, for several reasons, e.g. that the radium rays do not bleach the visual purple of the retina. London's experiments are misleading, since he does not particularize exactly the visual condition of his patients. Once the function of the rods and cones is destroyed, the eye becomes entirely unable to transmit visual concepts to the centers. London's patients who had a perception of light when brought before the radium screen would have experienced the same sensation before a screen illuminated by ordinary means, while the radium rays proper cannot be used to give visual picture, since they cannot be refracted. At present there is therefore no prospect of help for the blind through the intervention of radium.

Berliner klinische Wochenschrift, March 21, 1904.

The Serum Treatment of Hay Fever.—Lübbert and Prausnitz have collected the statistics regarding the value of the anti-pollen serum developed by Dunbar for the treatment of hay fever. The fact that this form of treatment has given excellent results with patients in all parts of the world in which it has been tried affords strong evidence in favor of the view that hay fever is a definite condition, having a constant exciting cause, though what the nature of the individual predisposition may be still remains unknown. The serum is obtained from horses innoculated with the pollen of various plants, and is used as a liquid and in powder form. So far its subcutaneous injection has not seemed advisable, and its use has been restricted to local application. Reports have been made on two hundred and eighty-five patients from different countries, with 60 per cent. in which complete relief was given, 29 per cent. of partial cures, and 11 per cent. of failures. From an analysis of the failures it appears that in most of these cases the directions were not adhered to, and that the remedy was tried only a few times and then given up, but a few instances remain in which the treatment seemed wholly without effect. The action of the serum is not curative in the sense that recurrence of the attacks is prevented, and its greatest value is as a prophylactic. Faithfully used during the attacks, however, it quickly relieves the symptoms and cuts short the seizure.

Münchener medizinische Wochenschrift, March 22, 1904.

Intestinal Secretory Neuroses.—Geissler reports a case which supports the view that the intestinal secretion can be influenced by nervous disorders and form the cause of diarrhœas. The patient was a physician who, after several years of dyspepsia and overwork, had become neurasthenic to such a degree that sanatorium treatment was necessary. After a certain length of time of treatment it was observed that small quantities of pure intestinal juice were voided, sometimes immediately following the movements, sometimes by themselves after having caused urgent tenesmus. The juice so obtained was found to be colorless, with an alkaline reaction, and contained albumin. Tested with blood fibrin, it showed peptic activity, and it partially emulsified croton oil, thus giving evidence of fat-digesting ability. Diastatic power was shown by the ability to change starch into sugar and to produce fermentation. Maltose was converted into fermentable sugar, and cane sugar was turned into glucose. The circumstances of the case, and particularly the fact that the fæces never showed undigested food, all contribute to the assumption that the secretion was the result of nervous derangement solely and not of hypermotility.

The Thermal Death Point of Tubercle Bacilli in Milk.—Rullman reports on a series of investigations undertaken to control the results of Hesse and of Smith to the effect that tubercle bacilli in milk are killed by exposure at a temperature of 60° C. for a period of twenty minutes. The fact that this limit is dangerously low is shown by Hesse's observation that when he heated infected milk only to 58° C., instead of to 60°, animals injected with the milk perished of tuberculosis. An accidental difference of two degrees in heating may easily occur in large establishments, and result in the delivery of an unsafe milk. The author used virulent bacilli from fresh sputum with which to infect the milk and started by heating the material according to the method of Hesse. Tuberculosis was induced in the animals injected with the milk so treated, and positive results were also obtained with various specimens of milk heated to successively higher temperatures. Finally a safe limit seemed to be reached by heating for one hour with constant stirring at 68° C., and the author regards this as the procedure to be recommended for routine use. If carefully brought to this temperature and rapidly cooled, very slight, if any, changes are produced in the flavor, the albumin and lecithin, or in the enzyme.

The Etiology of Orchitis Fibrosa.—Lesser studied the autopsy records of the Moabit Hospital from 1896–1902, in order to gain an insight into the etiology of this affection. Of late there has been a tendency to consider that causes other than syphilis, notably gonorrhœa, can induce fibrosis of the testicle, and many authorities concur in this view. Of the 2,979 autopsies of adult males investigated by the author, 133, that is 4.5 per cent. showed the lesion. In 70.6 per cent. of these, unmistakable evidence of a former syphilitic infection existed, but the ordinary average of syphilis in adults is only 9.6 per cent., so that a direct relationship between the two affections cannot be doubted. In regard to the cases in which no satisfactory evidence of syphilis exists after death, the author observes that syphilitic orchitis bears a very close analogy to syphilitic fibrosis of the liver. This condition often is found as the sole syphilitic lesion, yet no pathologist hesitates to ascribe it to its proper cause on this account, although the records show that in over 43 per cent. of the cases the diagnosis is based on the state of the liver alone. The greatest argument against the gonorrhœal etiology of the affection is found in the period of greatest frequency of its occurrence. To be a sequel of the urethral infection, the disease would have to manifest itself during the years in which gonorrhœa is most frequent, yet this coincidence does not exist, and it is a rarity for fibrous orchitis to be encountered before the thirtieth year. Other conditions, such as trauma, parotitis, tuberculosis, typhoid fever and influenza, have also etiological significance, but the author believes that ordinarily when fibrosis of the testicle is found without involvement of the epididymis or evidence of other etiology, the correct assumption is that the lesion is of syphilitic origin.

Resignation of Dr. Kreider.—Dr. George N. Kreider of Springfield, Ill., major and surgeon, assigned to the Fifth Infantry of the Illinois National Guard, has resigned, and Dr. Arthur F. Wilhelmy of Decatur has been designated to fill the vacancy on the examining board of the regiment caused by the resignation of Dr. Kreider.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held March 15, 1904.

DR. CHARLES H. LEWIS, CHAIRMAN.

A Case for Diagnosis.—Dr. SIGMUND EBSTEIN presented a man whose present history dated back three years when certain spots appeared on the left foot, especially over the dorsum, which remained for several days and then disappeared for months. The appearance of these spots was accompanied by sharp pains and cramps. Two years ago he had more pains and more spots which lasted for months. Six weeks ago he was seen at the Vanderbilt Clinic when he had several fissures on the ball of the foot. The patient was given salicylate and bromide of sodium in rhubarb and soda mixture.

Dr. PATTERSON, who had examined the case, said it was necessary to determine whether or not the cause was an organic nervous lesion. A very careful physical examination practically gave negative results. There were no areas of anæsthesia or disturbances of the temperature sense. On the dorsal aspect of the toes there was partial analgesia. The pain sense was somewhat retarded. He believed the conditions to be differentiated in this case were Raynaud's disease and erythromelalgia.

Dr. LEONARD WEBER supported the diagnosis of erythromelalgia, although nine out of ten cases affected the fingers rather than the toes. He could not understand why the toes should not be affected as often as the fingers. He believed it depended upon a sclerosed condition of the arteries of the lower extremities. Again he believed it might be due to some nervous disorder of specific origin.

Dr. WILLIAM M. LESZYNSKY said he would not make a diagnosis of erythromelalgia from the general appearance of the limbs. He believed it was a form of dermatoneurosis.

Dr. HERMANN M. BIGGS said he was reminded of a similar case seen last year in which the process began in the right hand and arm, and was followed by pain, swelling, and cyanosis of the right toe. The process gradually extended and involved the other toes of the right foot in a way similar to the one presented. Then the left foot became affected. Soon gangrene of the second and then the third toe appeared. There was a distinct syphilitic history, but antisyphilitic treatment had no influence upon the disease. He believed the condition was due to some arterial disease.

Dr. MORRIS MANGES thought the peripheral circulation was entirely too good for it to be a case of erythromelalgia.

Dr. EBSTEIN said that there was a syphilitic history, but antisyphilitic treatment had no influence upon the condition.

A Case of Trichinosis.—Dr. WM. B. NOYES showed a patient from the service of Dr. C. H. Lewis at Columbus Hospital. The patient was an Italian who had been nine months in this country. On admission, January 13, 1904, he had been ill five days with diarrhœa four or five stools per day. His eyelids became swollen and this was followed by swelling of the arms and legs. After three or four days the swelling began to subside and then he was seized with severe pains all over the legs and arms. Examination of the chest showed a few sibilant râles on the left side. Temperature was 101° in the morning to 104.4° in the evening, pulse 120, respirations 32. His tongue was coated and dry. The muscles of arms and shoulders were extremely sensitive, but negative to palpation. The urine had a specific gravity 1020 and contained no albumin. The Widal reaction was obtained 1 to 10. The blood count showed 6700 leucocytes, of which 82 per cent. were polynuclear, 3 per cent. large lymphocytes, 5 per cent. small lymphocytes, 10 per cent. eosinophiles. A diagnosis of trichinosis was suggested by Dr. Lewis from the pain in the muscles of the arm with the appearance of a myositis and the eosinophilia. The patient said he had had rheumatic pains ever since he had come to this country, but no swelling, and that his diet had consisted largely of pork for months. He remained in the hospital under observation for six weeks. His arm became more sensitive and the biceps contracted. The legs became œdematous and much swollen. On February 1 he found the condition of the patient as follows: He was well nourished, but looked ill. He was able to walk, but very unsteadily. He had marked contractions of the arms and legs. The grip of the right hand was weak, of the left, normal. Flexion was impossible, and only a moderate degree of extension. Forced extension developed rigidity of the arm. The muscles were hard and large, though smaller than before he was sick. The patient was able to dress himself and to perform the finer movements of the hand. There was no rigidity of the neck. Kernig's sign, or rigidity on hyperextension of the legs, was marked. The knee-jerks were lively. Careful examination of sensation showed hyperæsthesia to touch and pain all over, especially marked over the arms. He was as sensitive over the abdomen, especially the lower iliohypogastric region, as elsewhere. The contractures and pain were more in evidence when he was being examined than when he was alone in the ward. The patient gradually improved. All his clinical symptoms resembled the ordinary condition of hysterical contracture with certain hysterical points. On February 3 he made a blood count and found 28.5 per cent. of polynuclear leucocytes, 48 per cent. large lymphocytes, 5 per cent. small lymphocytes, and 16.5 per cent. eosinophiles, and 2 per cent. mast cells. On February 8 he excised a portion of his biceps and found trichinæ, thus confirming the provisional diagnosis of Dr. Lewis. Many sections were examined, and the trichinæ numbered about one to each section. Evidences of considerable myositis was found in the neghborhood of the encysted trichinæ with an accumulation of mast cells.

This case showed the three stages which writers had divided the clinical history of trichinosis. Stage 1. Intestinal irritation commencing soon after taking the infected meat. Stage 2. Characterized by severe muscular pains with pyrexia. Stage 3. Subsidence of the symptoms during which the trichinæ became encysted in the muscle. The diarrhœa was an early symptom and, if severe, might clear the intestinal tract of all parasites and abort the attack. About the eighth day puffiness of the face and eyelids appeared. The ninth and tenth days after infection pain in the muscle became marked and increased. It was at that stage that the patient was admitted. Almost any muscle might be affected, including the diaphragm, muscles of the eyes, and especially the arm and neck; but the œsophagus was said to be usually exempt. Œdema of the trunk and limbs occurred during the fourth or fifth week and might be quite general, but usually spared the genitals. The latter part of the attack of trichinosis might develop into more or less of a typhoid state after the acute symptoms of the early stages had subsided. Pulmonary complications were common. Convalescence might come by the fourth or fifth week as in the case reported, with permanent encystment of the trichinæ. When death occurred it may be at a later stage from some complication. The diagnosis of trichinosis, he said, was always difficult and, in some cases, impossible without a specimen of muscle showing the trichinæ. In the case reported the symptoms were referable to the lungs quite sufficient to explain the fever and other constitutional symptoms, and with the pains in various parts of the body influenza might have been diagnosed. But the persistence of the constitutional symptoms and the development of the general condition known as typhoid state made the diagnosis of typhoid fever in many cases seem probable, though the initial headache, epistaxis, rose-spots, and enlarged spleen

were absent. He said that, in this case, grippe followed by hysteria would have presented a symptom complex agreeing with every symptom of the history excepting eosinophilia. Hysterical contractures, or contracture following brain lesion, would simulate a myositis. He had now a case at the Demilt Dispensary where such a neurotic contracture, presumably hysterical, caused the biceps to be constantly in a state of tonic contracture, resembling a myositis from its hardness and apparent increase in size.

Intraspinal Injection of Lysol Solution in the Treatment of Cerebrospinal Meningitis, with a Report of Three Cases Treated by This Method.—Dr. MORRIS MANGES read this paper. He said that the perusal of the various monographs on the subject showed how very limited was the sphere of our therapeutic agents. So far as he had been able to learn from a review of the literature, methods of treatment had but little influence on the mortality, which, for the epidemic form, was estimated from 20 per cent. to 75 per cent. He said that we were indebted to Seager (*Lancet*, November 1, 1902) for a new method of treatment, the results of which were most encouraging. This treatment consisted in lumbar puncture and the withdrawal by aspiration from the spinal canal of varying quantities of cerebrospinal fluid, frequently amounting to 50 c.c. Artificial serum was then injected with the same syringe, the needle being left *in situ*, and the surrounding parts were washed with the serum; lastly, a quantity (from 9 to 12 c.c.) of a 1-per-cent. solution of lysol was injected through the same instrument and the needle withdrawn. The temperature would fall immediately, but rose again after one or two days, when the puncture and injections were to be repeated, and so on until only quite clear and limpid fluid was withdrawn after puncture, and then the injections were stopped. Seager called attention to the painfulness of the procedure, but Dr. Manges' experience in the two cases under his personal observation did not corroborate this. Of the thirty-one cases treated in Lisbon with lysol, 13 died—5 from dilatation of the cerebral ventricles, 2 from pulmonary tuberculosis, 1 from œdema of the glottis, 1 from purulent pneumonia, and 4 from the disease without complications. The 18 that recovered were *completely* cured.

Of the two cases that came under his personal observation one was a meningococcus infection and the other a virulent streptococcus. While it remained an open question whether the meningococcus case would have recovered without treatment, since the sporadic cases in adults not infrequently do so, yet the fact remained that the patient was losing ground in spite of the various treatments employed. After the first injection he seemed to hold his own, while after the second his recovery was rapid and uneventful. Of the second case he could speak with more assurance since, at the Mount Sinai Hospital, death had resulted in every instance of cerebrospinal meningitis in which the streptococcus was found in the fluid obtained by lumbar puncture. The condition of the child at the time of the first lysol injection was so desperate that no one who saw the case expected the child to survive the night; hence his complete recovery without any after-effects was all the more gratifying. It was to be noted that the washing out of the spinal canal with artificial serum was omitted in both cases The injections were all done without anæsthesia except the first one in the child, which was done under slight chloroform narcosis. No pain was complained of and no unpleasant after-effects were noted. Dr. Manges then gave the detailed histories of the two cases under his observation, and also the one treated by Dr. Seff at Lancaster, Pa., while he was home on a vacation. Dr. Seff was a member of the house staff at Mount Sinai Hospital.

An Observation on the Selection of Food in Tuberculosis.—Dr. JOHN B. HUBER contributed this observation and showed two maps of the lower portion of Manhattan Island, which were prepared by Miss Lillian Brandt, the statistician of the Charity Organization Society of New York City. The first of these maps represented by varying degrees of shading the varying densities of population in respective districts. The most densely populated district was thus shown to be the region about Grand and Rivington streets and east of the Bowery. This region was inhabited by Jewish people to the practical exclusion of all other races. It was said that one-fifteenth of all the Jews in the world are in New York City, and from five to seven hundred thousand of them; and the vast majority of these Jews were crowded into this district. Miss Brandt's second map represented the death-rate from consumption in these districts; in this map this same Jew-inhabited district was shown to be the one in which consumption was of all the regions in New York City the least rife. These maps tended to corroborate the findings of Korosi, Billings, Fishberg, and others to the effect that the Jews were of all people (except, perhaps, the Quakers) the least prone to tuberculosis. The Jewish people inhabiting this quarter were subject to all such conditions as would tend to tuberculosis, that obtained in all the other districts indicated. Indeed, among the Jews some of these conditions were greatly emphasized. For instance, they worked in sweat-shops, in vitiated atmospheres, bending over their machines for many hours, to the great detriment of normal respiration. These poor Jews were certainly no more cleanly than other people in the same stratum of life. With regard to their homes, this Jewish district was by far the most congested in the city. It occurred to Dr. Huber that there was one factor which existed among these Jews which did not obtain among other races—the "kosher" food. He had been informed by many that the very poor Jews, at least, obeyed implicitly the requirements of the Mosaic law concerning such foodstuffs as were rejected by their religious officials as "tiefa," or "unfit to eat." The percentage thus rejected was variously estimated at from 30 to 50 per cent. of the meat examined. This fact of food examination among the Jews seemed to him to have some bearing upon the opinions held by von Behring, Carrière, Raneuel, Theobald Smith, and others, to the effect that tuberculosis was oftentimes an ingestion disease. According to these workers, the tubercle bacillus in infected meat and milk, after having passed the gauntlet of the gastric juice, might be taken up by the lacteals and be conveyed to the thoracic duct in the chyme, and thence to the vena cava, the right heart, and, finally, the pulmonary parenchyma. There were some who went so far as to maintain that the ingestion of tuberculous foodstuffs was the only method of infection of the human organism; this view he considered absurd and unscientific. Even in inhalation tuberculosis, however, the air vesicles were generally not entered by the bacillus, the mode of dissemination being by means of the bronchial glands and the lymphatics of the upper-air passages, and thence to the vena cava, the right heart, and so to the pulmonary parenchyma, too. In conclusion, he referred to papers by the statistician, Mr. Hoffman, and by Drs. Flick, Ravinel, and Salmon, in the *Maryland Medical Journal* for February, 1904. In these papers much of the literature concerning ingestion tuberculosis was epitomized; and in them the names of some fifty workers in this field were set down.

On the Sanitary Surveillance of Tuberculosis in New York City. Illustrated by Exhibits Prepared for the St. Louis Exposition.—Dr. HERMANN M. BIGGS read this paper. After referring to the enormous death rate from tuberculosis, more than one-third of the deaths occurring in the best working period of life—fifteen to forty-five—and that nearly 45 per cent. of the deaths in Vienna during this same period were caused by it, he briefly gave an account of the manner of dealing with this dread disease in New York City.

(1) He said that there was a system of compulsory notification and registration. Last year there were re-

ported to the Board of Health 14,000 new cases of tuberculosis and 4,000 duplicates. These gave data as to age, sex, color, occupation, etc., and were recorded in two card indices. In one they were indexed according to street and number of residence, and in the other according to the name.

(2) Arrangements had been made with the Board of Health for the free examination of sputum for diagnosis, and had in view several purposes, a more cordial cooperation on the part of the medical profession, and, in this way, a large number of cases would be reported and again it would facilitate the early diagnosis. During the past year more than 11,000 specimens of sputum had been examined in the laboratories of the Department.

(3) The premises where reported patients resided, or where they had been removed, were visited by inspectors to determine the degree and extent of the possible infection of the apartments. Often, as a result, the owner of the premises was given an order requiring renovation, painting, papering, kalsomining of walls and ceilings, etc. In these cases the apartments are placarded forbidding their occupancy by other persons until the order had been complied with.

(4) When consumptives lived on the premises, then inspectors left circulars of information, gave verbal instruction, obtained any data which were lacking, determined the physical condition of the patient and what the sanitary conditions of the premises were, what precautions were being taken, whether the patient was a menace to members of his family or neighbors, etc., all of which facts were recorded on a card.

(5) Strenuous measures had been taken to educate the medical profession and the people as to the essential nature of tuberculosis and the measures to be taken for its prevention. A number of different forms of circulars had been printed, in different languages and for different classes of people. The public press received constantly full information regarding the work of the Department. The Tuberculosis Committee of the Charity Organization Society had rendered most efficient work. A large number of lectures had been given under the auspices of this committee. In various ways and through various channels a knowledge of tuberculosis and its nature and the measures to be adopted for its prevention had been widely disseminated among all classes of the community.

(6) Public institutions were inspected, and the completeness and accuracy of reports determined. Every death reported from tuberculosis was compared with the card index of reported cases, and it was found that 90 per cent. of the cases of tuberculosis had been reported previous to death.

(7) At the beginning of this work in 1894 he had prepared sectional maps of the city showing every house lot on a scale large enough so that reported cases and deaths could be plotted in each lot by conventional signs, indicating the month and year of report. A few blocks had been selected in which the largest number of cases had occurred, and he had them reproduced. On these each case and each death was indicated by a dot, and it was shown that in a single street block as many as 102 cases came to the notice of the Department from April, 1894, to January 1, 1899. The population of this block in January, 1900, was 1,165, showing that nearly 10 per cent. of its population was affected with this disease.

(8) The provisions for the care and treatment of consumptives in New York were lamentably deficient. Strenuous efforts were being made to remedy this. As a result of the action of the Department such cases now are only cared for in institutions especially devoted to this purpose. These have accommodations only for about 1,600 patients. The Department last year prepared plans for the erection of a special tuberculosis dispensary, and submitted a request for an appropriation. This was completed and opened March 1. Plans for two different sanitoria for the care of incipient cases have been under consideration.

(9) The Department had enacted ordinances forbidding spitting on sidewalks, floors of street cars and other public conveyances, ferry boats, ferry houses, elevated stations, etc., and considerable progress had been made in enforcing such ordinance, and educating the public up to their enforcement. It seemed to him that the time was coming and must come when public opinion would regard spitting on the floors of public places or conveyances or sidewalks as indecent and not to be tolerated. He firmly believed in the education of the public in this, which was of the greatest importance in the prevention not only of tuberculosis but also of acute respiratory diseases. He summarized some of the results accomplished briefly as follows: (1) Widely disseminated knowledge among all classes of the population as to the nature of tuberculosis and the measures to be taken for its prevention. (2) The provision for increased facilities for the care of these cases. (3) The development of a definite scheme and organization for dealing with tuberculosis. (4) The creation of an enlightened public sentiment toward the problem presented. (5) A reduction in the death rate since 1886 of more than 40 per cent. The tuberculous death rate for the ten years preceding 1886 was nearly 45 per 10,000 of population; for 1886 it was 44.1, and for 1902 it was 26.8.

What was further required in New York he summarized as follows:

1. A still more enlightened public sentiment, less fear of consumptives, and a more intelligent appreciation of where the danger is laid.

2. Better dwellings were needed for the poor; also more light and fresh air and space; better hygienic surroundings, better pavements, cleaner homes, better and more abundant food, etc.

3. The creation of a public sentiment to the effect that spitting on the floor of public conveyances, halls, etc., and on sidewalks, was indecent and not to be tolerated.

4. A closer supervision of consumptives by the sanitary authorities, and more frequent visits to their homes and places of business.

5. The education of the medical profession and public to a more thorough appreciation of the importance of a chronic cough and other signs of beginning tuberculosis in order that an earlier diagnosis might be made.

6. The suppression of the many widely advertised specifics and cures and special methods of treatment for tuberculosis, which served only to enrich their promotors and keep consumptives under unfavorable conditions for long periods of time.

7. More adequate provision for the care and treatment of tuberculous patients in special dispensaries, sanatoria, and recognized hospitals.

8. The more general enforcement of regulations for the compulsary removal and retention of these cases of pulmonary tuberculosis which were a menace to the public because of the inability or unwillingness to observe the necessary precautions.

9. The provision of some means for dealing with the economic features of this problem.

Dr. Biggs said that the removal of every case of tuberculosis meant a considerable expenditure, amounting perhaps to a loss of wages, interest of invested capital, cost of maintenance, etc., to at least $200 to $300. Thus during the year, for the care of two to three hundred cases, from $40,000 to $60,000 may be spent. This would result in the cure of a considerable number, say forty or fifty, the arrest of the disease in others, the sanitary education of all, the affording of comfortable surroundings and conditions for those who must ultimately die. Certainly this represented a large return for the money expended. He did not believe, so far as the ultimate reduction in the death rate was concerned, so much had been gained by such an expenditure as would have been gained by expending half this amount among the poorer classes, in sending medical inspectors and trained nurses to instruct and supervise the conduct of these consumptives at home, and the disinfec-

ion of their apartments when vacated, for in this way nore than ten times the number of consumptives could be eached.

There had already been a reduction in the death rate rom tuberculous diseases in New York City since 1886 of bout 40 per cent; and he had no hesitation in saying that vith a complete and efficient scheme for dealing with it, ncluding suitable hospital accommodations, the death rate night be further reduced within a similar period 40 per ent. more.

Dr. THOMAS DARLINGTON, President of the Health Department, in speaking of the spitting nuisance, said that, o far as the Board of Health was concerned, they were able nly to arrest about 200 people a week, and that it took early one day to have one man convicted, and then he as fined from $1 to $5, $1 if he was dressed poorly, $2 if e was better dressed, and $3 was added if they lied about t. With regard to patent medicines, etc., they were going o institute a campaign against their sale, and the newsapers were going to aid. He thought it would be wise to ave the people educated not to sweep and raise the dust; t would be far better to have some method adopted by hich the dust and dirt could be drawn up by suction umps. He condemned the use of carpets which, in many nstances, were tacked down and left for years without eing properly cleaned. He would rather have painted loors or hard-wood floors. When he was surgeon of the roton Aqueduct, in the building of which the workers reathed so much dust, if a man died and a post-mortem as held, he would often find what apparently was a tuberulous condition, concretions and stones in small cavities, ut in which no tubercle bacilli could be found. The effects f the constant irritation was shown on which might have een implanted the bacilli but which was not a true case of uberculosis. He believed this whole problem rested with he people and that they should be educated more, told to ave their windows open, etc.

Dr. S. A. KNOPF said that some means should be adopted y which less dust would be raised on the streets of New ork. There should be provided more street-sprinklers, nd he suggested taxing the owners of automobiles to raise he money for this purpose. With regard to the food roblem he only agreed with what had been stated in part. he people Dr. Huber referred to were almost all temperte. but he would find that the greatest mortality was mong the longshoremen, who were the most intemperate. r. Biggs' paper showed that when the people were taught garding this dread disease the mortality decreased. He lked for better housing for the laboring people, and hoped hat soon we would have larger accommodations for the oor. He said that in about two months a sanatorium ould be opened which would accommodate from sixty to ighty. He insisted that phthisiophobia still existed in oth private and official circles.

Dr. THOMAS DARLINGTON, in speaking again on the spitting question, said that the Board of Education had been pproached and asked to aid the Health Department in ating this nuisance. There were 500,000 children in the ublic schools of New York, and they were to be taught that hey should not spit on the sidewalks or public places, and hey were to be given cards with the sanitary code regardng spitting printed on the back for distribution among ffenders.

Dr. J. EDWARD STUBBERT spoke of the conditions of the abins on the ferry-boats, and especially the evils that ight result from sweeping with the brooms as now practised. He had studied the tuberculosis problem for many ears, and he did not think it could be solved by the use of anatoria, because a large proportion of these patients ither could not afford to go or would not go away to them, aving home and friends. Neither was it altitude that e should look to, but he believed it wise to take up the ork of establishing camps for occupancy during the summer months, or eight or nine months of the year. That ame idea could be followed out in private practice by insisting upon better ventilation of the rooms, by sleeping out of doors, etc. He believed that Dr. Biggs had struck the key-note when he said one could not depend upon sanatoria but upon the out-door treatment in the cities for this class of patients.

Dr. HERMANN M. BIGGS called attention to the exhibits that were prepared for the St. Louis exposition. They illustrated exactly the circulars and forms used by the Health Department. With regard to spitting he said he knew of no more difficult problem confronting the Health Board than how to provide adequate receptacles for ferry-houses, ferry-boats, platforms of elevated stations, etc.

PHILADELPHIA NEUROLOGICAL SOCIETY.

At a stated meeting, held March 22, Dr. J. H. W. Rhein exhibited "A Patient Showing Partial Paralysis Limited to the Arms, Following a Fall upon the Head and Back of the Neck." The case occurred in a middle-aged woman, who fell down a flight of stairs, suffering a rather severe commotion and contusion, but without loss of consciousness. There was at once marked loss of power in the upper extremities, in part due to pain induced by efforts at movement, and some increase in the reflexes in the lower extremities. Improvement in the motility of the upper extremities gradually took place, without alteration in electrical reactions; and only slight paresis remained, without atrophy. There had been pains in the affected parts, and some paræsthesia, but sensibility became entirely normal. It was suggested that the case might be one of hemorrhage into the white matter of the spinal cord, perhaps the lateral columns. Dr. C. W. Burr exhibited "A Patient for Diagnosis." The case was that of a young man who gave a history of deformity of the upper extremities at birth, attributed to fright on the part of the mother during the seventh month of pregnancy with this child. The patient stated also that he was late in learning to walk, namely at his sixth year. He presented a condition of extreme atrophy of all of the muscles of both upper extremities, with a corresponding degree of weakness and functional incapacity, as well as impairment of some of the reflexes in these parts, and abolition of others, and apparent shortening of the bones. There was further, some coalescence of the bones at the wrist, with want of mobility. The thumbs were partially withdrawn into the palms. Sensibility was unaltered, and the mental functions were commensurate with the educational opportunities of the patient. There was some shortening of the left lower extremity, with wasting of the muscles of the thigh. It was thought the case might be one of agenesis or intrauterine disease of the anterior horns of the spinal cord or possibly of muscular dystrophy. Dr. Alfred Gordon read a paper entitled "A Microscopical Study of a Spinal Cord Which Had Not Been Compressed by Displaced Vertebræ in a Case of Pott's Disease." The patient was a negro seaman, with a history of syphilis, and presenting symptoms of pulmonary and vertebral tuberculosis, who developed flaccid paralysis in the lower extremities, with bedsores, peripheral anæsthesia, and limiting hyperæsthesia. After death, the spinal cord was found to be free, although the lower three dorsal vertebræ were the seat of softening and displacement, and there was slight secondary meningitis. On microscopic examination of stained sections of the spinal cord at various levels degenerative alterations in the posterior and lateral columns were found below the seat of disease, but none at the actual seat. So-called Renaut's bodies were demonstrable in the sciatic nerve. It was thought that the process in the cord might be tuberculous, despite the failure to demonstrate the presence of giant-cells or of tubercle-bacilli, or toxic from the circulation of the products of the activity of the bacilli in the lesions of the vertebræ and the lungs. The possibility of syphilis playing some part in the morbid process was also mooted. Dr. Chas. K. Mills reported "A Case of Myasthenia Gravis, and a Case with Symptoms of Grave Hysteria and Bulbar

Involvement." The first patient was a man who became exhausted with undue readiness on attempting to take part in a procession. Subsequently there developed weakness of the muscles of the face and of the external ocular muscles, and also some difficulty in deglutition. The myotonic electrical reaction could not be obtained. The second patient was a woman who had been rather severely injured in alighting from a railway train and who presented weakness and fatigue of the facial muscles, including the tongue, together with segmental anæsthesia of the lower extremities and of one upper extremity, and in whom the symptoms were aggravated by the occurrence of a miscarriage and the expulsion of a dead and macerated fœtus. Dr. Mills also referred to several other cases that he had previously observed and which he thought belonged in the same category. Two of these had occurred in men who had been exposed to the influence of electrical currents of high tension, and who presented fairly characteristic symptoms. Another occurred in a man whose case had been considered as one of involvement of the third and fifth nerves, with associated spasm and paralysis. Dr. T. H. Weisenburg read for Dr. Theodore Diller of Pittsburg a communication entitled "Two Fatal Cases of Landry's Paralysis, with Autopsy Findings in One of Them." The one patient presented symptoms of peripheral polyneuritis, and it was thought that lesions like those found in the second might have been present. In the latter, alterations of a degenerative character were present in the ganglion-cells of the anterior horns of the spinal cord and in the centrifugal motor processes.

Pathological Society of Philadelphia.

At a stated meeting, held March 24, Dr. W. G. Pickett exhibited specimens from a case of "Crush of the Spinal Cord, with Secondary Degeneration." The patient was a man who had been struck in the back, suffering fracture dislocation of the spinal column at the level of the fifth, sixth, and seventh thoracic vertebræ, attended with flaccid paralysis of the lower extremities, abolition of the knee-jerks, anæsthesia, retention of urine, and incontinence of fæces. Death occurred twelve days after the inception of the injury, and on examination the cord was found compressed and surrounded by hemorrhage at the site of the displacement of the vertebral column. Histologic examination showed that while there was little degeneration of the cord in this situation there was marked ascending and descending degeneration below and above.

Dr. A. G. Ellis exhibited "Specimens from a Case of Rhinophyma." The patient was a man who had previously had acne rosacea and whose nose eventually became so large as to interfere with the act of taking food. A portion of the hyperplastic structure was removed without undue hemorrhage or other difficulty and union took place readily, the ultimate result being wholly satisfactory. Histologically the specimen was found to be constituted largely of fibrous tissue, with a large number of sebaceous glands.

Drs. T. O. Nock and Judson Daland exhibited a specimen of "Rupture of the Liver." The patient was an elderly man who had been kicked by a horse in the right mammary region. Although suffering great pain and profoundly shocked he was sent home in a carriage. No fracture of the ribs could be detected on physical examination, but the signs indicated the existence of pneumonia in the lower lobe of the right lung. The patient lived for six days, and after death rupture of the liver was found. The adventitious fissure was filled with blood-clot, but there was no free hemorrhage into the abdominal cavity. There were also a few submucous hemorrhages in the wall of the stomach, but the remaining viscera presented no abnormality.

Dr. Guthrie McConnell exhibited "A Cyst of the Urachus and Bilateral Hydronephrosis in a Nine-months' Old Baby." The little patient presented during life a swelling in the right iliac fossa, which was attributed to the vermiform appendix. On account of the gravity of the child's condition operation was at once undertaken and the mass punctured and evacuated, a moderate amount of purulent matter escaping. The abscess communicated with the bladder. Death resulting, the ureters were found dilated and the base of the bladder and the prostate the seat of three tumors, sections of which on histologic examination presented appearances suggestive of myxo-sarcoma.

Dr. George B. Wood exhibited a specimen of "Retro-pharyngeal Abscess." The patient was a little colored child that presented a swelling on the posterior wall of the pharynx in the middle line. On puncture a moderate amount of pus was evacuated, and the child improved so much that it was sent home, where death took place, in convulsions it was reported, although it was thought asphyxia had resulted. Port-mortem examination disclosed the existence of a retropharyngeal abscess with enlargement of lymphatic glands in various parts of the body, tubercle-bacilli being demonstrated in the lesions. There was a single small suspicious nodule in one lung.

Philadelphia County Medical Society.

At a stated meeting, held March 23, Dr. W. W. Keen read a paper entitled "A Case of Total Laryngectomy (Unsuccessful) and a Case of Abdominal Hysterectomy (Successful), in Both of Which Massage of the Heart for Chloroform-collapse Was Employed, with a Note of Twenty-five Other Cases of Cardiac Massage Thus Far Recorded." The case of laryngectomy occurred in a man who had been struck accidentally with a brick in the left parietal region. Aphasia developed, with some huskiness of voice, and, the symptoms growing worse, the skull was trephined and the pressure relieved. Ether and oxygen were employed as the anæsthetic, but the patient exhibited a tendency readily to become cyanotic. The aphasia was much improved, but the hoarseness increased. The larynx was now found to be the seat of a new growth and partial laryngectomy was undertaken. There was again considerable difficulty with the anæsthetic, interference with breathing resulting if the narcosis were pushed and the patient struggling when the anæsthetic was withdrawn. One vocal band was found extensively involved and the other in slight degree. Accordingly, one-half of the larynx was removed. Recurrence taking place after a time, total laryngectomy was decided upon. chloroform being employed as the anæsthetic, and a preliminary laryngotracheotomy being performed. Again difficulty was experienced with the breathing, and finally the heart ceased beating. Efforts at resuscitation were at once instituted including artificial respiration and faradization of the phrenic nerves, but these failing, an incision was made in the abdominal wall, through which one hand was introduced and the heart compressed through the diaphragm between this hand and the other hand placed upon the chest wall. The patient, however, failed to react. Dr. Keen reported also a case communicated to him by Dr. Igelsrud of Sweden, in which the action of the heart failing, during the performance of abdominal hysterectomy under chloroform-anæsthesia massage of the heart was undertaken, together with other measures, and the patient recovered. A second case in which a like result was brought about in a similar manner has been recorded by Dr Crile of Cleveland, and a third an English surgeon by Mr. Arbuthnot Lane. All of the remaining cases terminated fatally. The massage may be applied to the heart through the unopened diaphragm; or the diaphragm may be incised, the hand being passed through the incision; or a flap may be turned back upon the chest over the heart. Dr. Keen pointed out the necessity of employing other vivifying measures in order to stimulate also the respiration and vasomotor activity. He exhibited the rubber apparatus of Dr. Crile, by means of which the body can be enveloped in an air-sac and the vascular pressure maintained at a physiological level.

Dr. L. J. Hammond read a paper entitled "The Surgical Relations of the Vermiform Appendix to Perforations in Typhoid Fever." He reported the case of a woman in whom symptoms of perforation of the bowel developed during the course of an attack of typhoid fever. Operation was undertaken, and a large rent found in the ileum and sutured. There were present, in addition, evidences of previous inflammation of the vermiform appendix with adhesions of the cæcum and the colon. Recovery failed to take place, and the unfortunate result was attributed in large measure to the complicating adhesions. A second case was reported in which symptoms of appendicitis occurred at the inception of an attack of typhoid fever. Operation was performed promptly in this instance and recovery ensued without complication.

Drs. J. H. Musser and De Forest Willard presented a communication entitled "Amœbic Abscess of the Liver," reporting the case of a woman, fifty-five years old, who was seized with an attack apparently of gastroenteritis, which left behind symptoms of colitis that were thought to depend upon dysentery. Examination of the stools disclosed the presence of non-motile bodies resembling amœbæ coli. In the further progress of the case the area of hepatic dulness became increased, and a mass could be felt in the upper portion of the abdomen that appeared to correspond with the left lobe of the liver. The possibility of amœbic abscess of the liver suggested itself, and accordingly the abdomen was opened and puncture of what was thought to be the liver was practised. A moderate amount of grumous chocolate-colored fluid was obtained, admixed with a small amount of pus. The cavity entered was walled off and drained, and recovery ensued in the course of a comparatively short time. The material removed was examined and found to contain pus-corpuscles, but no amœbæ and no echinococcus-hooklets and no pancreatic juice could be detected. A definite conclusion as to the nature and seat of the morbid process was not reached, although, in addition to abscess of the liver, pancreatic cyst and an accumulation of unknown nature in the gastrohepatic omental space suggested themselves.

Dr. Francis T. Stewart read a paper entitled "A Case of Primary Typhoid Cholecystitis, with Calculi," reporting the case of a woman not known ever to have had an attack of typhoid fever, who presented symptoms of cholecystitis, for the relief of which operation was undertaken. The gall-bladder was found distended with fluid, from which typhoid-bacilli in pure culture were obtained, and a number of calculi also were present. The contents of the gall-bladder were evacuated, the wounds closed, and the patient recovered without complication.

Chicago Medical Society.

At a meeting, held March 16, Dr. Wm. L. Ballenger exhibited a young woman who, nine years ago, was vaccinated. Vaccination was followed by a discharge from the ear. Four years ago the patient came under his observation, was treated consecutively for a year and a half, with only temporary cessation of the discharge. Three years ago he did a radical mastoid operation, finding cholesteatomatous masses in the middle ear and mastoid cavities, with suppuration, caries, and perforation in the middle fossa of the brain. There was marked meningeal irritation. The operation afforded relief, but subsequently trouble developed in the mastoid portion of the wound, necessitating a second operation. A few days following the second operation he resorted to Thiersch grafting in the mastoid portion, and a week or two later he did a Thiersch graft in the middle ear. At present the middle ear was lined with skin; also the mastoid and anterior portion of the wound. The case was interesting on account of the Fallopian canal being exposed, showing the facial nerve. The Eustachian tube was likewise visible. He expected to close the Eustachian tube later, and having done this, he will then close the mastoid wound, and by means of paraffin injections hoped to avoid much deformity. The patient seemed entirely well in other respects.

Dr. Joseph H. Miller exhibited numerous stereopticon slides showing the processes of maturation and fertilization of the ovum.

Dr. William T. Eckley read a paper entitled "The Accessory Sinuses." After entering extensively into their anatomy, he presented the following conclusions: The accessory sinuses of the nose in man are phylogenetically very ancient structures and figure physiologically as feeble, subsidiary respiratory organs. The maxillary sinus in the higher vertebrates has its prototype in the amphibian accessory nasal chamber, in which it was an olfactory organ; hence phylogenetically the antrum in man is an obsolete organ of smell. For as yet unaccountable reasons, the sinuses develop *pari passu* with the generative organs, and there is evidence of an intimate physiological relation between these remote anatomical organs. The variations, even in healthy sinuses, are so great, that it were hazardous to attempt an analytical classification looking to definite size, shape, or openings. For embryological reasons, each sinus is a law unto itself. The sinuses are supplied by the trifacial nerve; hence reflex phenomena between them and the peripheral cervical nerves is possible. As a diagnostic expedient, the specialist should always bear in mind the possibility, in the sinuses of man, of reversion to structural fixed types in the lower vertebrates. Operations on the sphenoidal sinus are anatomically unjustifiable. Sound teeth should never be sacrificed, and the nasal route for gaining entrance to the antrum is never dangerous.

Dr. William L. Ballenger spoke on the "Surgical Treatment of the Nasal Accessory Sinuses." He discussed the indications of intranasal operations for disease of the maxillary sinus; the intranasal treatment of the ethmoid cells, the intranasal operation for the frontal sinus, the major operations resorted to for the cure of sinus disease, and mentioned the Desault, the Caldwell-Luc, Kunt, Kunt-Luc, and Kellian operations. In the discussion, Dr. Eugene S. Talbot exhibited several lantern slides, showing the evolution, embryology, period of stress, and the method by which arrests of the face, nose, jaws, and teeth are produced. He said these arrests and excessive development are due to an unbalanced nervous system. He also showed the two typical forms of faces in neurotics and degenerates, in which these deformities are always present. While making examinations of skulls in this country and in Europe some two decades ago, special attention was given to abscessed and diseased antra due to dead pulps in the teeth. Of the 11,000 skulls examined for deformities, only 3,000 were in a broken condition, so that the antra could be examined, making six thousand antra in all. Of this number 1,274, or about 21 per cent., had abscessed molar teeth. Of this number 76, or about 6 per cent., extended into and apparently discharged into the antrum. Dr. M. H. Fletcher, he said, had examined 5,000 skulls, making 1,000 antra. He found 252 upper molars abscessed, making 25 per cent. of antra which had abscesses in this locality. Out of 252 possible cases, perforation into the antrum was found only twelve times, thus showing over 4½ per cent. of abscessed teeth in this locality, which are connected with the antrum. In the treatment of 367 cases of pulpless teeth in connection with the superior molars, in the past twenty-two years, he found only three cases of diseased antrum, making less than 3 per cent. Taking, therefore, the large number of teeth treated by dentists because of dead pulps and alveolar abscess, the number of diseased antra due to alveolar abscess was very small.

Joint Meeting of Chicago Laryngological and Chicago Medical Societies.

At the March joint meeting of these societies, with the the President, Dr. John Edwin Rhodes, in the chair, Dr. Henry Gradle read a paper entitled "When to Operate and When Not to Operate on the Mastoid Bone." He reviewed the literature, and said that the reports contained therein teach, first, that suppuration of the middle ear, both acute and chronic, involves danger to life. Secondly, that even in the desperate cases reported greater success attends mastoid operations, although many of them must extend into the cranial cavity, and, thirdly, that properly timed surgical intervention would have prevented this serious extension of the disease. The indications for opening the mastoid for acute disease, he said, can be best defined on the basis of a brief review of the various modes of determination of acute mastoiditis. In at least one-third of all instances, acute mastoiditis subsides gradually after a climax of three or four days, provided there is free drainage from the middle ear. He discussed the operative indications, and, among other things, said that in chronic disease of the middle ear and mastoid, the operative indications are to be regarded from a different point of view from those in acute cases. A simple opening of the mastoid antrum, although often curative, is generally not the proper operation. In most cases a cure is obtained quicker and with greater certainty by the radical operation, which converts the antrum, the attic, and the middle ear proper into one continuous and accessible space with exenteration of contents. A prompt radical operation is the only safe course in all instances in which irritative symptoms indicate active extension of the disease. This immediate indication is given to all chronic instances of otitic suppuration by persistent dizziness, pain or local tenderness, one-sided headache, or any symptoms suspicious of intracranial involvement.

Dr. E. Fletcher Ingals followed with a paper entitled "Treatment of the Suppurative Diseases of the Accessory Sinuses of the Nose." Referring to the treatment of suppuration of the antrum, he said that in acute cases the patient should be kept quiet, the pain relieved by hot or cold compresses over the cheek, and the swelling and turgescence relieved by local applications in the region of the ostium maxillare. In chronic cases Christopher Heath recommends entering the antrum above the alveolus through the canine fossa; the tendency to closure being obviated by making an opening a centimeter or more in diameter. The radical operation consists of opening through the canine fossa and curetting thoroughly the lining of the antrum, removing at the same time any dead bone or obstructing septa. As to treatment of suppuration of the ethmoidal cells, some cases recover spontaneously, but most of them continue for many months, and even years, unless thoroughly treated. In acute cases relief may frequently be obtained by local medication that will reduce the swelling and thus allow the pent-up secretions to escape. Of the treatment of suppuration of the sphenoidal sinus, he said that Kiaer and Lapelle, in 364 autopsies on bodies dead from various diseases, found over 13 per cent. affected by suppuration of this sinus, which would indicate that the affection is very generally overlooked. In regard to the treatment of suppuration of the frontal sinus, on account of the dependent position of the ostium frontale and the direction of the canalis nasofrontalis, not a few patients affected with acute suppuration of this sinus will recover spontaneously. In others the cure is much facilitated by local remedies which reduce the swelling, such as suprarenalin and cocaine, which may be used several times daily, in the same manner as recommended for suppuration of the ethmoidal cells or for closure by swelling of the ostium maxillare, but in a considerable number of these cases the obstruction is due to nasal mucous polypi or to chronic thickening of the middle turbinated body, so that it will not be relieved in this manner. In such cases the polypi should be removed or the anterior end of the middle turbinated cut off, or both. If the canal is completely closed, and in any case in which the disease does not yield within four or five months to treatment, it is probable that partial septa cause pus pockets in the frontal sinus, or that the walls of the cavity are much diseased. In these conditions a radical operation by an external opening through the anterior wall of the sinus is necessary.

Dr. Norval H. Pierce discussed "The Symptoms and Diagnosis of the Suppurative Diseases of the Accessory Sinuses of the Nose." The author pointed out those symptoms which are common to suppurative disease of all the accessory sinuses, and followed the lines of description laid down by Hajek. Under local symptoms he discussed headache, neuralgia, secretion, etc. Under general symptoms he referred to fever, congestion and depression, nasal discharge, objective symptoms, and also spoke of atypical hypertrophies of the middle meatus; and dilatation of the maxillary sinus. In speaking of the diagnosis reference was made to the value of transillumination. The symptoms of disease of the frontal sinus were detailed and its diagnosis discussed; also disease of the ethmoid cells, latent or closed empyema, open empyema, disease of the sphenoidal sinus, and, lastly, attention was directed to one complication of sphenoidal empyema, namely, the extension of the inflammatory process to the orbit.

Therapeutic Hints.

Puerperal Infection.—Ochsner's treatment is worthy of mention. The lymphatic circulation is retarded by inhibiting muscular action by rest. The opium treatment of peritonitis was in principle not unlike this method. Two drugs are of especial value, strychnine and alcohol, both pushed. The alcohol can be varied to suit the taste and frequently changed. Strychnine should be given in doses of $\frac{1}{30}$ to $\frac{1}{10}$ grain every 2 to 4 hours; after full effects, smaller doses. Quinine may be added. Elimination is favored by bowel evacuation and diuresis. Acetate of sodium added to the fluid for enteroclysis or hypodermoclysis increases the effect. In the sheet-pack for antipyrexis, wet a double-gauze sheet at short intervals with water at the body temperature. Surgical measures should be instituted as required.—Charles Jewett, in *Brooklyn Medical Journal*.

For Intertrigo in Children.—

Ammon. sulpho-ichthyol.....ad 6.0
M. Warm and shake before using. Apply on cotton for 5 minutes twice a day for 8 to 14 days.

—M. Katzenstein, in *Wiener klinische Wochenschrift*.

Treatment of Spasmodic Asthma.—Dr. A. T. Wilkinson found in his experience the nitrites somewhat disappointing. Occasionally the free use of drachm doses of liq. ethyl nitrit. freshly mixed, has given decided relief. Amyl nitrite is more powerful, but acts too strongly elsewh

Nitroglycerin is of value in lessening the degree of spasm. The relief given by potassium iodide is also due to the relaxation of spasm. For fear of establishing a drug habit, morphine, cocaine, alcohol, and inhalations of chloroform should be only resorted to in rare instances. Belladonna gives relief, but should not be given to old people in whom the asthma is secondary to bronchitis.—*The Medical Chronicle.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending April 9, 1904:

	Cases.	Deaths.
Measles	1706	49
Diphtheria and croup	387	70
Scarlet fever	474	30
Smallpox	...	...
Varicella	101	...
Tuberculosis	417	200
Typhoid fever	22	8
Cerebrospinal meningitis	...	29

Streptococcus Diarrhœa.—Sanford Blum says that when a virulent germ comes on the field of enteritis, as, for example, the streptococcus, it dominates the intestine, the less active organisms playing a minor part. Two modes of ingress are open for bacteria into the digestive tract; the organism may be habitually present and become virulent at an opportune time, or the organism may be ingested with the food. The diagnosis of streptococcus enteritis can be made positively only with the microscope; and the Widal and diazo tests, together with the temperature curve, will differentiate it from typhoid fever. When severe diarrhœa occurs during hot weather in children, without error in diet or other apparent cause, bacterial infection of the digestive tract should be suspected. In general, bacterial gastroenteritis is a severe disease, as is shown by its great mortality. Even the pyocyaneus bacillus causes remarkable mortality when firmly lodged in the digestive tract of children. The author found the iliocæcal region most intensely affected, but the entire length of the mucous membrane of the gastrointestinal tract was more or less involved. The lesions presented all stages of inflammation, to ulceration and necrosis, which may extend as deep as the muscular layer, and was most often found in the ileum and colon. The lesions in the stomach, duodenum, and jejunum were slight.—*Archives of Pediatrics.*

N-rays for Brain Trouble.—A despatch to *The Sun*, April 3, says concerning the discovery of the *n*-rays by M. Blondelot that "the rays are now proved to be nothing more nor less than part of the invisible spectrum of sunlight, a little more ultra than ultra-violet rays. They are somewhere between heat and electric rays, slower than rays of radiant heat and faster than Hertzian waves. They can pass through aluminum as sunlight through glass and can be focussed by aluminum lens. These rays traverse lead, tinfoil, platinum, and copper without difficulty and do not require complicated apparatus like the Röntgen rays. They stream from an ordinary incandescent gas lamp. More remarkable still, they can be spontaneously produced from a number of substances, such as wood or glass when twisted or subjected to pressure. Untempered steel does not produce the rays, but tempered steel continually emits them. Time has no effect, knives tempered over 1,000 years ago emitting them as freely as steel tempered yesterday. When thrown directly and solely upon the eye they enable it to see in a darkened room objects which had previously been invisible. Professor Charpentier discovered that the human body emits the rays in quantities proportionate to the activity of that part of the body whence they come. He has also proved that they are emitted from the speech-center of the brain whenever a person speaks. When the speaker emits rays they vary according to the pitch of the note. Dr. Bruce of Edinburgh has taken up the subject. He expects that when it is known exactly what rays come from various parts of the brain in normal conditions it will be possible to use variations of quantity and quality as a means of detecting the injury or disease of different parts of the brain.

Movement of Population in Japan.—The Japanese Government has recently published its annual on the "Movement of Population in the Empire of Japan" during the year 1900. In the review of this work in the *New York Times*, April 3, the reviewer says: "Incidentally this work disposes of some curious notions recently set forth, not only by newspaper writers, but even by medical an literary men of repute who, having been in Japan more or less remotely in the past, have not kept up with the movement of population and events. For example, it has been recently stated that beriberi, which was formerly confined to the low-lying districts at the mouths of rivers, has been, because of improved means of communication by railways and steamers, converted into a national scourge, and will more than decimate the Japanese armies abroad during the coming springtime. As a matter of fact, beriberi has been so far eliminated from the Japanese navy that, as a rule, it is only the old and experienced surgeons who have treated a case on shipboard. The very minute tables of diseases, covering 95 pages, shows that in the whole empire, excluding Formosa, there were in 1900 but 6,500 deaths from this disease, a figure which, it is safe to say, is scarcely one-tenth of what the facts would have shown fifty, possibly even twenty, years ago.

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended April 9, 1904:

ACUTE INFECTIOUS OSTEOMYELITIS OF THE SPINE AND ACUTE SUPPURATIVE PERIMENINGITIS.*

By J. RAMSAY HUNT, M.D.,
NEW YORK.
CLINICAL INSTRUCTOR IN NERVOUS DISEASES IN THE CORNELL UNIVERSITY MEDICAL COLLEGE; NEUROLOGIST TO THE CITY HOSPITAL; ASSISTANT PHYSICIAN TO THE MONTEFIORE HOME.

INTRODUCTION: While the acute infectious osteomyelitis is a well-recognized and not infrequent affection of bone tissue in general, it but rarely attacks the vertebral column.

The comprehensive statistics of Frohner and Haaga, published in 1889, are often cited in support of this statement. Among 545 cases, representing an involvement of 661 long bones and 51 short bones, the spine was found involved but once, the now classical observation of Lannelongue.

While the vertebral involvement is certainly rare, these quotations give but an imperfect idea of its true frequency. The real nature of many of these cases is never recognized, owing to the proximity of the inflammatory process to the spinal cord and the thoracic, abdominal, and pelvic organs.

The slight primary bone or periosteal focus is overlooked or subordinated to the more extensive secondary purulent infiltrations in the adjacent vital organs and body cavities.

Thus one finds recorded, more especially in the older literature, not a few cases, unquestionably originating in a primary vertebral osteomyelitis or periostitis and catalogued under the following clinical headings: Retropharyngeal abscess; deep cervical abscess; mediastinal abscess; perforating empyema; retroperitoneal abscess; paranephritic abscess; primary suppurative psoitis; pelvic abscess; and acute rheumatism of the spine.

If this is true of cases with autopsy the number of errors in unrecorded clinical observations may well be imagined.

There is no more striking instance of this misinterpretation than is afforded by the so-called acute primary suppurative perimeningitis. My reasons for assigning this group of perimeningeal suppurations to the acute osteomyelitis will be discussed later.

The general pathological character of the osteomyelitic process is the same irrespective of the skeletal localization; but the direct relation of the spine to important organs lends a peculiar interest to this region, owing to the great diagnostic difficulties encountered and the very high mortality.

Two cases have come under my own observation which I will record briefly before proceeding to a general discussion of the subject.

I wish to express my thanks to Dr. C. L. Dana and Dr. F. W. Jackson for their courtesy in permitting me to observe and record these cases; also to the Surgeons Drs. F. W. Gwyer and C. H. Chetwood for according me the same privilege.

CASE I.—Admitted to Bellevue Hospital, service of Dr. C. L. Dana, March 31, 1902. Operation by Dr. Frederick W. Gwyer, April 4, 1902.

Summary.—Boy, aged eighteen. Sudden onset with severe pains in sacral region, following a trauma. High fever, rapid pulse, great prostration, leucocytosis 40,000, splenic tumor, œdema, and bogginess, over sacrum. Symptoms of compression of cauda equina.

Diagnosis.—Acute osteomyelitis of the sacrum with an extradural accumulation of pus. Operation, cure.

The patient was a stable-boy, aged eighteen, who three weeks before had fallen backward landing squarely on the sacral bone. The pain was intense at the time, but was able to resume his work, and in about an hour the ill effects had worn off. He was frailly built and ill-nourished, otherwise previous history was negative. No venereal infection.

Ten days after the injury he awoke with severe pain in the lumbosacral region, shooting into the buttocks, especially on the left side. He reported for work, but, owing to the continuous pain in sacral region, was forced to desist.

After sleeping a few hours the pains were more violent and he returned home. Later the legs grew numb and he experienced delay and difficulty in urination.

Two kinds of pain could be distinguished, one a deep-seated constant boring pain over the sacrum, the other sharp and lancinating, these electric darts shooting into the gluteal region on both sides, more especially the left.

Condition on admission March 31, 1902: Patient is pale, poorly nourished, and greatly prostrated. Temperature ranging from 102° F. to 104° F. Pulse 120. Lies on the side with the upper portion of the spine bent backward and the head slightly retracted. Heart, lungs, and urine are negative. Spleen is enlarged and palpable below the margin of the ribs.

Careful inspection and palpation of the spine reveals no deformity until the sacrum is reached; here the soft parts are slightly swollen and œdematous, especially to the left over the sacroiliac articulation.

The slightest pressure over this area causes agonizing pain.

The column is somewhat rigid, especially in the lumbosacral region, but movements are fairly well executed, accompanied, however, by excruciating pain.

The pupils present a slight inequality, the right wider than the left. No cranial nerve symptoms. No rigidity of the neck. The mind is perfectly clear.

Both lower extremities are weak, especially the left. This paresis is uniformly distributed over all segments, no objective sensory disturbances. The knee-jerks and the Achilles jerks are absent on both sides. Abdominal and cremasteric reflexes present. Plantar stimulation (induces) flexion of the toes. Kernig's symptom absent.

April 1 and 2: Still suffering extreme pain in lumbosacral region, radiating into the buttocks. Head still retracted but without rigidity of the neck.

*Read before the Section on Orthopedic Surgery of the New York Academy of Medicine, February 19, 1904.

Temperature 104° F. No change in the objective symptoms referrable to the lower extremities. Leucocytosis of 40,000. The diagnosis was made of acute osteomyelitis of the sacrum, with an extra-dural accumulation of pus, compressing the cauda equina. The patient was transferred to the surgical ward for operation.

April 3: Operation performed by Dr. Gwyer. On incising the soft parts over the sacral swelling, a large quantity of thick fetid pus welled up into the wound. About 6 ounces were evacuated. The surrounding muscular tissue was the seat of a purulent infiltration, and a portion of the left dorsal aspect of the sacrum was rough and denuded of periosteum, as was also the lamina of the fifth lumbar. The spines and laminæ of the fourth and fifth lumbar vertebræ were resected, allowing the escape of 2 or 3 drachms of pus from the spinal canal outside the dura. The dura was not incised.

Case I. Osteomyelitis of the sacrum and fifth lumbar arch. Slight lateral curvature of the left thigh and leg.

April 4: Still has local pain at the seat of operation, but the agonizing sacral pain has disappeared. Retention of urine. The right knee-jerk is now elicitable on reinforcement. The left and both Achilles jerks are still absent.

April 6: Wound is doing well, some pus and many shreds of dead tissue and sloughs were washed out during the irrigation.

April 7: Catheterization still necessary. At times passes small quantities of urine voluntarily. Right knee-jerk present.

Left knee-jerk and both achilles jerks absent.

The left thigh and leg measure one-quarter of an inch less than the right.

April 15: Still discharging pus; good drainage; wound granulating.

April 17: Patient has no pain. Both lower extremities are weak, the left more so. This paresis is most noticeable in the extensors of the knee and foot. A bacteriological examination of pus evacuated at the time of operation contained a pure culture of the staphylococcus pyogenes aureus.*

April 25: Electrical reactions—The muscle group of the right thigh respond promptly to the galvanic and faradic currents. The extensor, flexor, and adductor group of the left thigh respond feebly to electrical stimulation, both galvanic and faradic most apparent in the extensors of the knee. The anterior and posterior tibial group on both sides respond sluggishly to the faradic current, both directly (muscle) and indirectly (nerve). The anterior and posterior tibial groups react fully to strong galvanic currents applied to their respective nerve trunks. When applied directly to the muscle the response is slow and vermicular with distinct r versal of the poles (reactions of degeneration).

June 2, 1902: Wound almost healed. No vesic symptoms. Can walk, but with a tendency t foot-drop. The left leg is distinctly weaker tha the right and is visibly atrophic.

The atrophy is noted in the left thigh and le and to a less extent in the right leg. (See Fig. 1.)

Right knee-jerk good response. Left knee-je feeble response. The achilles jerk is feeble but elic table on both sides.

The weakness of the left lower extremity is ge eral, but most pronounced in the extensors of t foot and knee.

June 11, 1902: Measurements—Right thigh, 1 inches; left thigh, 13 inches; right leg, 11¾ inche left leg, 11¼ inches. While standing, and aft exposure of the body, muscular twitchings devel in the gluteal muscles. The posterior muscles the thigh and the legs on both sides. The muscul movements consist of coarse fibrillary contractio clonic movements, and a succession of musc waves, the so-called myokymia. Moderate scolios the convexity directed toward the right.

Electrical Reactions.—Diminished electrical r sponse of muscles of the left thigh to both curren In left leg no reaction obtained by either curre through the nerves. Directly applied, qualitati changes are noted in both the anterior and p terior tibial group. Right leg diminished, el trical responses, but no qualitative changes. P tient was installed as doorboy in the hospital, a performed this duty for several months. T weakness in his lower extremities improved. Sp perfectly mobile, causing him no pain or unea ness. Discharged cured.

Case II.—Admitted to Bellevue Hospital Se vice of Dr. Frank W. Jackson, January 3, 19 Operation by Dr. Charles H. Chetwood, Janua 8, 1903.

Summary.—Boy, aged five years, previou healthy. Sudden onset with fever and severe p in mid-dorsal region. Five days later, sympto of spinal-cord compression (paraplegia). Hi fever, great prostration, leucocytosis 40,000. Sli œdema, glazing of skin and bogginess, with extre tenderness over the mid-dorsal region of the sp

Diagnosis.—Primary vertebral osteomyelitis w an extra-dural accumulation of pus. Operati cure.

The patient, G. M., was a boy aged five years, sturdy constitution, who had enjoyed excell previous health. No family history of tuberculo No history of a trauma could be obtained fr mother or child.

On the evening of December 30, 1902, return home after an afternoon of play in the streets, co plaining of not feeling well. That night was re less, crying out several times in his sleep.

The next morning was dressed as usual, but mained listless and apathetic, showing no inclin tion to play. That afternoon complained of in the back and was put to bed. In the eve had fever and a slight epistaxis.

The pains in the back continued growing severe, and any attempt to move him caused treme exacerbations of suffering, accompanied screams.

He also had sharp shooting pains in the l zones of the chest, more especially on the left sid

The fever continued, child became some dull, and on January 2 passed urine only twi twenty-four hours. No convulsions.

Was admitted to Bellevue Hospital Januar 1903.

*Dr. H. H. Buxton, Bacteriological Laboratory of the Cornell University Medical School.

On admission the child was greatly prostrated, face flushed, with a temperature of 104° F., and a pulse of 130.

Complains of occipital headaches and severe pains over the lower zones of the chest, especially on the left side.

There was priapism, and catheterization was necessary. The extremities were freely movable. The examination of the internal organs and cranial nerves were negative. The leucocyte count numbered 30,000.

January 6, 1903: The spine is slightly arched and rigid, and the head is retracted and the neck stiff. There is a complete flaccid paraplegia, with loss of the tendon reflexes. The Babinsky reflex is present on both sides. The line of anæsthesia goes to the eighth dorsal spine posteriorly, and the eighth rib anteriorly, and apparently involves all sensations, although the age and condition of the child precludes certainty in this respect.

The abdomen is distended and the lower ribs do not rise with the inspirations. Above the line of anæsthesia is present a distinct hyperæsthetic band, which corresponds in level with the sharp shooting pains complained of by the patient before admission.

The spinal column presents no gross evidences of disease, save the rigidity and extreme pain on movement.

On the upper dorsal region, from the fifth to the eighth dorsal spines, there is extreme tenderness, the slightest pressure causing excruciating pain. The tenderness is by no means confined to the spines themselves, but is felt also on both sides of them, more especially the left.

On movement pain is referred to the same level. Over this area the soft parts are somewhat swollen, puffy, and œdematous, but without any fluctuation.

The temperature had fallen to 98° F. in the morning, rising to 103° F. in the afternoon. Kernig's symptom was absent.

NOTE.—January 5: Temperature rose to 102° in afternoon. Pulse 120, respiration 30. The child lies flat on the back, and is dull and apathetic, inclined to somnolence. Spontaneous pain in the back is very much diminished, and when questioned complains only of the sharp pains in the lower dorsal region, any attempt at movement, however, is accompanied by screams.

The motor and sensory paralysis remains unchanged. There is constant priapism, and catheterization is necessary. Leucocyte count 29,000. Urine normal.

January 8: Transferred to the surgical ward for operation. The œdema over the fifth, sixth, seventh, and eighth dorsal spines has increased, and a slight sense of fluctuation is detected.

The superjacent skin is glistening and somewhat mottled.

Tongue is heavily coated. Slight cyanotic tinge of lips and face. Spleen not palpable. Leucocytes 30,000.

The plantar reflex is absent on the left side, the abdominal and cremasteric reflexes on both sides.

Operation by Dr. Chetwood, January 8 at 4 P.M.: The anæsthetic was nitrous oxide, followed by ether inhalation. An incision was made in the median line, exposing the spines of the fifth to the eighth dorsal vertebræ. On cutting through the muscles about four ounces of fetid pus was evacuated, and after retraction of the soft parts, more pus could be seen escaping between the laminæ of the fifth and sixth dorsal vertebræ.

The spines and laminæ of both the sixth and seventh dorsal were rough and partially denuded of periosteum. A laminectomy of the sixth dorsal was performed, allowing a further escape of extradural pus.

The exposed external surface of the dura was covered with velvety granulations. The dura mater was not incised.

January 9, 1903: Marked improvement in the general condition. Complains of very little pain. Motor symptoms remain unchanged. The line of anæsthesia has fallen to the level of Poupart's ligament. Both knee-jerks and achilles jerks are absent. Both plantar reflexes are active and of the extensive type. Catheterized.

January 13, 1903: Slight, barely perceptible dorsal flexion of the feet and flexion of the knee was first observed. Anæsthesia to Poupart's ligament. Catheterized.

January 17: Urine passed without catheter. Bacteriological examination of the pus evacuated at the time of operation was made by Dr. H. H. Buxton of the Cornell Laboratory. A pure culture of the staphylococcus pyogenes aureus was the result.

January 29, 1903: Spontaneous, involuntary movements of legs occur. Nurse finds that the legs change their position. Slight skin stimuli produce reflex movements. On making passive movements the flexors of both knees show a slight tendency to contraction, is easily overcome and disappears after a time. No voluntary movements observed. The left knee-jerk has returned and is exaggerated. The right knee-jerk and both achilles jerks are still absent. Coarse tactili impressions are recognized over the lower extremities. Pain and temperature sense uncertain. Deep sensibility is not greatly disturbed.

February 8: No knee-jerks elicitable to-day, and the lower extremities are quite flaccid.

February 13: Barely perceptible voluntary movements of toes and feet. Slight flexor contractures of knees. The knee-jerks are elicitable with difficulty.

March 21: Legs have gained from day to day, all movements are carried out. The left leg is weaker than the right. Sensation is practically normal. Incontinence of urine.

February 15, 1904: The child has been under constant observation since the last note, the motor power in the lower extremities gradually improving. Is able to stand alone and walk about, but the gait is slow and spastic, particularly the left leg. Sensation is completely restored. There is still incontinence of urine. Otherwise the child is in perfect health. The spine is straight and mobile and without the slightest curvature.

History.—The history of the affection begins with the publication of Lannelongue's monograph in 1879, entitled "L'Osteomyelite Aigue de la Croissance."

Less accurate observations were recorded before this by Valleix in 1835 and Brietze in 1872.

Since then the literature has been enriched by many excellent theses and case reports.

Those deserving of special mention are the monographs of Cadeilhan (1880), Tournadour (1890), Chipault (1897), and Grisel (1903) in France, Hahn (1895 and 1899) in Germany, and Makins and Abbott (1896) in England.

Hahn, in his later monograph, published in 1899, collected and analyzed forty-one cases.

I have collected the cases of acute osteomyelitis of the spine, which have been recorded since this publication, bringing the total number up to sixty-eight. Of these, three were not accessible in the original and three cited by Hahn were excluded

because of insufficient data, so that the present study is based on an analysis of sixty-two cases.

Etiology and Pathogenesis.—One of the most potent factors, seemingly almost essential to the production of an osteomyelitis is the growing period of life.

These years during which the spine is undergoing gradual ossification and development.

This process is usually not complete until about the thirtieth year.

According to Gray, at birth each vertebra is represented by three ununited primary cartilaginous portions, one for the body and one for each lamina and its processes.

During the first year the laminæ are united posteriorly, and about the third year the neural arch is joined to the centrum. Before the age of puberty no other changes occur except a growth of these primary centers.

At the sixteenth year four secondary ossification centers appear, one for each transverse, and two sometimes fusing for each spinous process.

At twenty-one a thin epiphysial plate of bone develops on the upper and under surface of the centrum.

At about the thirtieth year the vertebra is completely formed.

Certain obscure nutritional conditions are present in these growing bones which attract and favor the development of pyogenic bacteria.

Hence the age is an etiological factor of the first importance. In 59 cases

18	occurred	in	the	1st	decade	of life;
31	"	"	"	2d	"	" "
7	"	"	"	3d	"	" "
1	"	"	"	4th	"	" "
2	"	"	"	5th	"	" "

Among the exciting causes may be mentioned injury to the spine, either a direct blow or a lifting strain. Excessive fatigue. Exposure to wet and cold. Some local septic process, as a furuncle, angina, or the puerperium. The larger number of cases, however, develop spontaneously.

The affection is twice as frequent in males.

In 56 cases there were 38 males and 18 females.

The direct excitant is naturally always microorganismal. In 20 cases in which a bacteriological examination was recorded:

The staphylococcus pyogenes aureus	was demonstrated	in	15	cases.
The staphylococcus pyogenus albus	"	"	1	case.
The streptococcus	"	"	2	cases.
Staphylococci and streptococci	"	"	1	case.
Micrococcus Tetragenus	"	"	1	case.

Pathological Anatomy.—Any of the numerous bones engaged in the formation of the spinal column may be the seat of the disease. The coccyx alone seems to be exempt, probably owing to its protected situation and functional insignificance.

In 61 cases the disease was localized in the cervical region, 12 times; dorsal region, 15 times; lumbar region, 24 times; sacral region, 10 times. Several vertebræ may be implicated in the process or a small part of a single segment may present the only focus, as a lamina, a transverse or a spinous process.

Cases are recorded in which the erector spinæ group of muscles was riddled with abscesses, the contents of the neural canal bathed in pus with numerous metastatic abscesses, all originating in an insignificant and scarcely demonstrable bone or periosteal focus. Among the more potent factors influencing the prognosis may be mentioned the portion of the vertebræ involved and the extent and intensity of the inflammatory process itself.

Some writers speak of an anterior and posterior osteomyelitis, indicating involvement of the centrum or neural arch respectively, finding a justification for this division in the subsequent course and termination.

In the anterior osteomyelitis the suppuration is much deeper, giving rise to retropharyngeal, psoas, mediastinal and pelvic abscesses with consecutive visceral complications.

In the posterior osteomyelitis, on the other hand, the process is more superficial, the pus infiltrating the muscles of the back; usually indicated externally by œdema and fluctuation.

This variety is more accessible and more readily evacuated, and the prognosis is correspondingly more favorable. Spinal complications in this variety are, however, not infrequent.

The extent of the bone and periosteal involvement varies greatly in different cases.

Three degrees may be recognized. A mild form, more in the nature of an acute periostitis, the bone not undergoing denudation.

A more severe grade, involving the superficial layers of bone, leading to the formation of subperiosteal abscesses, roughening and denudation.

In the gravest form the bone and marrow are riddled with abscesses and purulent foci, and recovery if it occurs, is accompanied by sequestra formation.

In this form the danger of a generalization of the process and pyæmia are most imminent. The mild form will be referred to later in discussing the etiology of the so-called acute primary suppurative perimeningitis.

The situation of the spinal cord and meninges within their canal, render them peculiarly liable to implication.

Of sixty-two cases, fifteen presented grave symptoms of compression of the cord. In nine additional cases an extradural collection of pus was demonstrated at autopsy or operation, without symptoms of cord compression having been recorded.

If the osteomyelitis originates in the inner wall of the canal, neural complications are inevitable.

Pus may, however, find its way into the canal from without, through the intervertebral foramina or by penetrating the ligamentous attachments of the vertebræ.

Infection may also occur through the medium of the blood-vessels.

The result is an extradural abscess at the affected level. In not a few cases, however, instead of a circumscribed collection of pus, widespread suppuration of the loose areolar tissue occurs, through the whole extent of the canal, constituting the acute suppurative perimeningitis.

As the spinal dura is firmly attached anteriorly to the posterior common ligament and above to the margins of the upper cervical vertebræ and foramen magnum, the exudate is distributed chiefly over the postero-lateral aspect of the dura, and above is effectually shut off from the cranial cavity.

The cord suffers chiefly through compression and inflammatory œdema. In only one case was the dura perforated. In three cases there was noted suppurative leptomeningitis.

Hence the dura presents a fairly effectual barrier and any operative interference should relieve only the compression. Incision of the dura would only increase the danger of a general meningitis.

Septic thrombosis of the spinal plexus of veins is a frequent complication, which by blocking the circulation leads to distention and prominence of the superficial veins of the back over the affected area. This constitutes an important objective symptom and its significance was recognized and described by Lannelongue.

In contrast to the tuberculous osteitis, angu

deformities, and curvature of the spine are the exception.

This condition was mentioned in only six of sixty-two cases. Four of these recovered. One case, complicated by an empyema with resection of the ribs, was permanent, and one of my cases with a cervical localization and cauda symptoms was discharged with a slight lateral curvature.

This freedom from spinal deformity is largely accounted for by the acuteness and gravity of the process, enforcing the recumbent posture and by the irritative nature of the inflammatory process stimulating periosteal proliferation.

Also those cases with rapid breaking down of the bodies, and naturally most favorable to the development of this condition usually prove rapidly fatal.

Symptomatology.—In the great majority of cases the onset is acute; ushered in with high fever, rapid pulse, and the other evidences of a severe general infection. The onset may be preceded for several days by mild prodromal symptoms, as headache, rigors, and a general feeling of malaise.

Co-incident with the acute general symptoms, where local pains are felt in the spine. These are very intense, having the character of osteocopic pains in general. As a rule they are most severe over the affected area, but their local character may be masked by their intensity, producing a general rachialgia.

Often accompanying the intense throbbing and boring pains of bone inflammation, are the sharp lancinating pains following implication of the nerve roots within the canal or the intervertebral foramina. These root pains are readily distinguished from the bone pains, and, depending on the level involved, are referred to the extremities or encircle the trunk. I would particularly emphasize the occurrence and often early appearance of these lancinating pains which, with the acute general infection, have in many instances given rise to diagnostic errors. Among these may be enumerated: cerebrospinal meningitis, pleurisy, pneumonia, peritonitis, and appendicitis. Later with the formation of abscesses and the symptoms of general pyæmia, the true nature of the affection was recognized.

Abdominal pain and distension has received occasional mention in the dorsal localization, and is ascribed to compression of the sympathetic ganglia or their communicating branches.

Rigidity of the spine is almost a constant symptom and when severe may be accompanied by opisthotonus and retraction of the head.

Some observers note in addition to the fixation of the spine, strange and bizarre attitudes assumed by the patient, evidently in an effort to relieve tension and tender parts from pressure.

A symptom of paramount importance, and one to which I am inclined to lay the greatest stress is the extreme local tenderness over the inflamed area of the spine. It is especially valuable because an early symptom and scarcely ever absent. This is not a hyperæsthesia but an intense and agonizing pain induced by direct pressure over the column.

In contradistinction to tuberculosis, jarring of the spine is usually negative, a fact emphasized by Chase. Movements of the spine are generally limited, owing to the rigidity, and are accompanied by pain, usually referred to the affected level.

The further progress of the disease is characterized by an increasing sepsis, abscess formation, visceral complications and pyæmia.

The continued high fever, rapid pulse, rigors and sweats; the splenic tumor and increasing leucocytosis, the extreme exhaustion and progressive emaciation, all indicate but too clearly the profoundly septic state.

With the formation of abscesses, external evidences of deep-seated suppuration are usually evident, more conspicuous, and more constant in the posterior osteomyelitis.

There are reddening and glazing of the skin, slight pitting on pressure, bogginess or distinct fluctuation. Dilatation of the superficial cutaneous veins is sometimes noted due to thrombus formation in the peridural plexus.

The danger of visceral complications resulting from the deep-seated suppuration, have been sufficiently indicated in discussing the pathological anatomy. The symptomatology of such visceral lesions is naturally peculiar to the organ involved and requires no special comment.

It is well, however, to bear in mind the acute osteomyelitis, in cases of acute retropharyngeal, mediastinal, paranephritic, and pelvic suppurations, of obscure origin in young adults, as history teaches us that this is often overlooked in view of the more important visceral manifestations.

If the vertebral symptoms are preceded or accompanied by the formation of distinct osteomyelitic fever in other bones, the true nature of the case is immediately apparent.

Such multiplicity of bone lesions is, however, rather infrequent, occurring in only fourteen of sixty-two cases.

Neural complications, because of their frequency and importance, are deserving of special mention.

The almost uniform cause of such symptoms is to be found in an extradural accumulation of pus, originating in the diseased bone focus.

The natural effect is a compression of the cord, the symptoms of which are focal, corresponding in level with the vertebral pain and tenderness.

It must be emphasized, however, that an extradural abscess may exist without symptoms of compression. (In nine of sixty-two cases.)

The sharp posterior root pains and vesical symptoms are usually the first indications of the beginning compression. Paræsthesiæ and progressive weakness in the parts below the lesion soon follow, usually advancing until a complete motor and sensory paralysis results. In brief, the symptoms of a complete transverse lesion of the cord are present, which, varying with the level, is indicated by a paraplegia or a quadriplegia, as in one of my cases cauda equina symptoms may exist and in two other cases unilateral involvement of the roots of the brachial plexus may follow suppuration in the deeper structures of the neck.

An interesting observation in some of these cases, is the gradual rise in the level of the paralysis, as is observed in Landry's disease. This increase of the paralytic phenomena is to be directly ascribed to the burrowing of the pus in the loose peridural cellular tissue.

Such an extension is accompanied by extreme general rachialgia, rigidity, contractural states and hyperæsthesia, as in meningitis.

In some cases infection of the loose peridural areolar tissue takes place almost immediately, is not circumscribed, spreading like wildfire in all directions. When this occurs the focal manifestations, often slight, may be completely masked by the symptoms of acute general meningeal irritation. This group of cases is a frequent source of error; their real nature in many cases is not recognized until the autopsy, and some not even then.

The above description represents, in a general way, the usual type or clinical picture of the disease. Certain aberrant cases deserve notice however: One is an extremely acute fulminating type, death occurring in a few days, apparently from the virulence of the infection. Others run a more sub-

acute course with mild septic and irritative symptoms, progressing with the formation of large abscesses and resembling in some particulars the tuberculous osteitis.

Diagnosis.—The diagnosis of the acute vertebral osteomyelitis, by virtue of the extent and manifold relations of the spine and the depth of the suppurative process is often one of extreme difficulty.

The primary condition and underlying cause is often obscured by the presence of grave neural and visceral complications. This is especially true, if the case first comes under observation at this period.

Diagnostic errors are likewise very common in the earlier stages, the combination of a septic state and referred root pains simulating other acute infections, as: pleurisy, pneumonia, peritonitis, appendicitis, and meningitis.

Hence the recognition and proper interpretation of the initial bone symptoms are of paramount importance.

The abrupt onset in a young adult of intense local vertebral pain and tenderness with increasing symptoms of infection should always suggest the osteomyelitis.

With the persistence of extreme local tenderness, increasing sepsis, and the superficial signs of deep-seated suppuration, the diagnosis becomes reasonably sure. Multiplicity of bone lesions would render the nature of the case certain.

It must be remarked, however, that with the formation of abscesses an amelioration of the intensity of the spinal symptoms may take place.

This subsidence of the acute vertebral pain was present in both of my cases, and may be very misleading. The local pain on movement and direct pressure, however, persisted.

The differential diagnosis of this affection, because of its manifold possibilities and protean nature, cannot be discussed in detail.

I know of no other spinal affection which should cause serious confusion.

Tuberculous caries with proper care should never be confounded with it. The same is true of the various forms of infectious osteitis of the vertebræ.

The acute articular rheumatism is said rarely to invade the spine, and with the other joint manifestations might for a time be misleading.

The possibility of pyogenic invasion of preëxisting tuberculous spondylitis must be borne in mind. Chipault has reported one case.

Prognosis.—The prognosis of the acute vertebral osteomyelitis is extremely grave. Of sixty-two cases, of which fifty were operated, thirty proved fatal, constituting a mortality of 50 per cent.

The statistics of cases recorded during the past five years are distinctly more favorable. Of twenty-eight cases, all but two of which were operated, there were twenty recoveries, and only eight deaths.

This reduction in the mortality is no doubt owing to greater accuracy in diagnosis, and more prompt and efficient surgical measures, so that even better results may be looked for in the future.

The following factors may be emphasized as influencing the prognosis:

The virulence of the infection; the degree and extent of the osteomyelitis process; the visceral involvement; the level of the spine affected.

Of 12 cases in the cervical region, 7 died;
" 15 " " " dorsal " 3 "
" 24 " " " lumbar " 13 "
" 10 " " " sacral " 7 "

Treatment.—Any treatment which does not include the evacuation and drainage of the abscess cavities and removal of diseased bone is to be regarded as futile and temporizing. The longer operation is delayed the greater becomes the danger of visceral entanglement and pyæmia.

Therefore an early diagnosis and immediate surgical interference yield the most favorable results.

If the cases are abandoned to their fate death is practically certain; only two cases are recorded with spontaneous rupture of a dorsal abscess and recovery.

Remarks on the Relation of the Acute Primary Suppurative Perimeningitis to the Acute Osteomyelitis of the Spine.—In the discussion of the vertebral osteomyelitis, the perimeningeal suppuration and the peridural abscess have received frequent mention. It is one of the commoner complications and was noted in twenty-four of sixty-two cases.

Such inflammatory and suppurative processes outside of and encircling the dura, were described as early as 1833 by Albers, and termed by him the perimeningitis medullæ spinalis. Frank recorded similar cases under the title of peripachymeningitis both of these terms are in use at the present day.

The infection of the peridural areolar tissue is secondary, and may usually be traced to some pathological process in the immediate neighborhood as the spine, thoracic or abdominal viscera, or sacral bedsores.

In addition to these cases in which a source of the infection could be demonstrated, a few observations have been recorded during the past twenty years, the majority by French observers, in which no such primary focus was apparent.

Clinically their course was rapidly fatal, and attended by intense spinal irritative and paralytic symptoms, the autopsy revealing nothing but peridural cellular tissue bathed in pus.

So that in the course of time, as the number of carefully recorded observations increase, an idiopathic infectious suppurative process has come to be rcognized, originating in the vascular areolar tissue encompassing the dura mater.

In other words, this loose cellular tissue has come to be regarded as a structure in which a pyogenic process may arise *per se*, independent of any other focus.

Systematic writers on nervous diseases are, generally speaking, very guarded in their brief remarks devoted to this subject, describing the general pathological characters of the peripachymeningitis, its mode of origin, and usually secondary nature. Others again touch on the obscure nature and uncertain origin of the so-called primary form. Gowers says distinctly in the last edition of his text-book, published in 1899: "It is certain that acute general external meningitis occurs as a primary disease, and may run an intensely rapid course with profuse suppuration between the membranes and the bone."

The various structures of the body vary greatly in their susceptibility to pyogenic processes. The bones and serous membranes are good examples of tissues extremely liable.

The rarity alone of the primary perimeningitis would justify a reasonable doubt as to its idiopathic origin, which would, by no means, be removed when the immediate relation to the periosteum and bone is given due consideration.

Futhermore there is nothing specific in the highly vascular areolar-tissue; it is in no sense an endothelial structure, as might be erroneously inferred from the terms perimeningitis peripachymeningitis, and external meningitis, the intense fibrous dura forming a fairly effectual barrier to the spread of inflammatory processes in either direction.

In discussing the pathology of the acute osteomyelitis, the variations in the intensity of the bone lesions were emphasized.

The periosteum alone or the periosteum and the superficial layers of bones may represent the depth of the suppurative process, and the surface area may be proportionately small.

It is therefore quite conceivable, in a complicated mechanism like the spine, with its innumerable surfaces and projections, that a small focus of periostitis or superficial necrosis could readily escape detection or be regarded as a secondary affect.

It is also quite obvious that if the abscess formation were superficial, it would, meeting with less resistance, burst at an earlier period into neighboring structures.

If this were to occur in the spinal canal the result is easily conjectured.

These preliminary considerations I think show that the primary perimeningitis as a clinical and pathological entity may justly be regarded with a spirit of skepticism, until strong positive evidence is brought to the contrary.

A careful study and analysis of the recorded cases go far to disprove the theory of an idiopathic origin.

There are twenty-four cases of this affection recorded in medical literature, or cited in monographs devoted to this subject. A few of these belong to the older literature, and have only an historical interest, while others, because of an insufficiency of detail, are not entitled to serious consideration.

Of the total number only thirteen may be regarded as worthy of analysis. (Recorded in abstract in the appendix.)

One of these, a case reported by Putzel, may be immediately relegated to the primary spinal affections, because of the focal character of the symptoms and the eventual evacuation of an abscess containing a sequestrum. Another case recorded by Lewitsky was complicated by a deep sacral decubitus following primary medullary symptoms which would sufficiently account for the peridural suppuration.

Of the remaining eleven, all terminated fatally, after an acute illness, the majority succumbing in the second week of the disease.

Sex.—Ten of the cases were in males; one of the cases was a girl.

Age.—Five cases in the first decade of life; four cases in the second decade of life; one case in the third decade of life.

As in the acute osteomyelitis the affection belongs essentially to the adolescent period of life.

In all of the cases—and I would particularly emphasize the fact—there were present distinct local symptoms referable to a certain level of the spine.

These local manifestations, while no doubt somewhat masked by the general severity of the process, stood out quite clearly in the clinical picture.

They are variously indicated, usually by local pain and tenderness, and local abscess formation in the adjacent muscles. In six cases there were sensory and motor paralysis referable to a compression myelitis, the level of the compression corresponding to the other local manifestations.

In one of these cases, evidently a cervical localization, the neck was enormously swollen, deglutition was difficult—there were root pains in the course of the occipital nerves, and cervical abscesses.

In two of the cases fistulous tracts in the muscles led directly to roughened and denuded bone. In another case, evidently a sacral localization, there was noted a perirectal abscess, and a deep sacral abscess, following a typical osteomyelitic manifestation in the left tibia.

If these eleven cases are tabulated according to their local manifestations, the ratio of involvement of the various regions of the spine bears a striking analogy to that of the acute osteomyelitis.

In both, the lumbar region is most frequently diseased, the dorsal coming next in order.

Of the eleven cases, local manifestations were referable to the cervical region, one case; dorsal reigon, three cases; lumbar region, six cases; sacral reigon, one case.

From the foregoing considerations, I feel justified in asserting that there is not a single recorded case of acute primary suppurative perimeningitis, which does not accord perfectly in its clinical and pathological manifestations, to our present conception of the acute osteomyelitis of the spine; and if Erb's dictum of thirty years ago be true, that there is no just ground for assuming that such idiopathic inflammations may not occur, it may be said with equal truth, that with the evidence now in hand there is no valid reason for assuming that such an idiopathic inflammation ever has occurred.

It may be argued by some that the pressure of a minute focus of osteomyelitis does not materially affect the nature of the case, and that the lesion and symptoms are essentially those of a suppurative perimeningitis.

That, therefore, our present conception and title is the correct one, as best indicating the general character of the process.

Such a point of view, I consider not only to be scientifically inaccurate, but, from the practical standpoint, a very dangerous one.

It is of the first importance, that the greatest stress should be laid upon the focal spinal symptoms, as not only indicating the true nature of the affection, but also the immediate necessity and site for operation.

I believe that with due attention to the early diagnostic features indicated in the discussion of the acute osteomyelitis, the true nature of these cases may be recognized and the proper surgical measures instituted; and that under such conditions the prognosis would be by no means unfavorable.

All of the recorded cases terminated fatally. In only one case was an operation attempted, the immediate effect of which was favorable, death occurring as the result of an endocardial complication.

In the operative management of this group of cases, the double laminectomy in the mianner suggested by Chipault may be employed with benefit as insuring the most perfect drainage.

General Summary.—The vertebral column is rarely the seat of the acute infectious osteomyelitis. Sixty-two cases have been collected and analyzed in the present communication. Great diagnostic difficulties are sometimes encountered, owing to the immediate relation of the spine to the vital organs of the thoracic and abdominal cavities and the spinal cord and its membranes. Hence retropharyngeal, mediastinal, retroperitoneal and paranephritic abscesses, pelvic abscesses, peridural suppurations, and general pyæmia may be mentioned among the more important complications. Peridural abscess or suppuration occurred in twenty-four of sixty-two cases. Of these, fifteen cases presented grave symptoms of compression of the spinal cord. The essentials of the clinical picture consist of the symptoms of a severe general infection, associated

with the local signs of an inflammatory process of the spine: *e.g.* excruciating pain and tenderness, œdema and fluctuation. The mortality of the affection is 50 per cent. Immediate and thorough surgical interference is the only treatment. Some systematic writers accept, and cases are recorded of a primary suppurative perimeningitis or idiopathic suppuration of the loose peridural areolar tissue. Twenty-four cases of the so-called primary suppurative perimeningitis were collected, eleven of which present sufficient data for purposes of analysis.

An attempt is made to establish the relationship of these cases of primary suppurative perimemingitis to the acute osteomyelitis of the spine. Based on the similarity of the clinical and pathological manifestations and the *a priori* improbability of such idiopathic peridural suppuration. For the reasons detailed at length in the paper, it seems advisable to abolish entirely from our present nomenclature the term idiopathic or primary suppurative peril meningitis, and to regard all such cases as identica- with the acute osteomyelitis of the spine.

ABSTRACT OF THE CASES OF PRIMARY SUPPURATIVE PERIMENINGITIS.

Constant, *Gaz. Med. de Paris*, 1835.

Girl, aged ten. Acute onset with chills, fever, and headache. Pains in the extremities.

Headaches continued, very severe in the occipital region radiating laterally and producing the sensation of a constriction. Severe pains in cervical, lumbar, and inguinal regions. Extreme general hyperæsthesia. Right thigh is flexed; movements of left leg limited; arms free; retraction of neck, general rigidity; neck is enormously swollen; deglutition is almost impossible; later, legs in constant flexion; incontinence of urine.

Autopsy.—The epidural space from the cervical region to the cauda equina was bathed in pus.

Bristow, Transactions of the London Pathological Society, 1855, p. 45:

Man, aged thirty-six. No previous history. For some days severe pain in back, especially localized in the lumbar region, which was tender. On movement pain referred to lumbar spine. High fever, rapid pulse, progressive weakness and emaciation. Paraplegia developed gradually.

Autopsy.—External surface of dura bathed in pus. Some pus also in subdural space.

The erector spinæ groups, and the ileopsoas muscles were riddled with abscesses. Small accumulations of pus beneath the pleura as the intercostal nerves emerge from the intervertebral foramina.

Traube, "Gesammelte Beiträge II," p. 1039:

Man, aged twenty-three. Acute onset after exposure to cold with headaches and violent lumbar pains, also pain in neck with stiffness and pains in the legs. Difficult micturition. High fever and severe constitutional symptoms.

One month after onset an abscess presented itself in the left lumbar region; very tender; incised and pus evacuated.

Autopsy.—Purulent infiltration of lumbar muscles on the left side, leading down by fistulous tracts to the twelfth dorsal, the transverse process of which is roughened and partially denuded. Pus in the spinal canal outside dura and in the psoas muscles.

Lewitsky, *Berliner klinische Wochenschrift*, 1877, s. 227:

Man, aged forty-four. Fall on lumbar region; pain for two days, then disappeared. Admitted, January 18. Paralysis of right leg and paresis of left leg with corresponding sensory disturbance. No pain, no spinal tenderness or rigidity. Gradually the legs grew worse and the left arm became paralyzed. Absolutely no pain or tenderness on percussion of the spine. General condition encouraging.

January 24: A large, very extensive and deep sacral decubitus developed, laying bare the bone. After this the temperature rose. There were rigors. Temperature continued high with chills. Death, February 6.

Autopsy.—Extradural accumulation of pus most marked in lower portion of the spinal canal. Also a purulent leptomeningitis. The cord was hyperæmic. No microscopical examination recorded.

NOTE: *The history of this case suggests a primary medullary affection with a resulting decubitus. The suppuration in the spinal canal resulting secondarily from the gangrene of the soft parts and exposure of the sacrum.*

W. H. Spencer—*Lancet*, 1879, Vol. I, P. 836:

Boy, aged fourteen, Acute onset with pains in the back, shooting down the legs, Worked for one week, suffering with lumbar pains. Occasional rigors. On admission severe pain in lumbar spine with great tenderness on both sides. Motility and sensation undisturbed. Sphincters normal. Pains in lumbar region continued, a few days later extending to dorsal region and neck. Rigidity of neck. The temperature, rapid pulse, septic symptoms and diarrhœa resembled typhoid fever. Died.

Autopsy.—A large collection of pus in muscles of lumbar region. The spinal canal outside the dura was filled with pus from cervical region to the cauda, oozing through the intervertebral foramina. The spine was normal; cord normal; a recent clot of blood in left occipital fossa.

L. Putzel, MEDICAL RECORD, Vol. 13, 1878:

History.—Man aged twenty-two. Onset March 8, with pains in shoulders, cervical and upper dorsal regions. Torticollis.

March 13: Swelling appeared on back of neck. Diagnosed as deep abscess. Pyrexia, rapid pulse, and an eruption resembling typhoid.

March 20 to April 1: Complete paralysis of the bladder. Girdle at lower part of chest. Paralysis of left arm and leg with sensory disturbances.

April 2: Regained power in left arm and leg, which became hyperæsthetic.

July 19: Discharged, greatly improved. Paræsthesia and fibrillary twitchings on left side.

September 19: Examination by Dr. Putzel. Paresis of left arm and left leg with paræsthesia on same side. Tender mass in left rhomboid muscle.

February 28: A small abscess in region of third and fourth dorsal was opened and drained, discharging thick pus.

March 1: A small piece of bone was discharged from the sinus. Complete return of motor power; recovery.

Lemoine et Lannois, *Revue de Médecine*, 1882, P. 535:

Man, aged twenty-two. Two days after a fall, felt pains in the back. The day following chills and difficulty in breathing. Legs grew weak. Four days after onset was completely paraplegic. movements cause pain at the level of the first and second dorsal vertebræ. This area is also extremely tender on pressure. No other tender points along the spine.

Anæsthesia complete to the mammary level. Plantar and tendon reflexes of legs are lost. A hyperæsthetic band above the level of anæsthesia.

Retention of urine. Priapism. On movement pains are constantly referred to the first and second dorsal.

The line of anæsthesia ascends. Severe pains and burning in the arms which become weak. Later paralysis of both arms. And the line of anæsthesia rose 10 cm. above the line of the nipples.

Autopsy.—No evidences of a bone lesion discoverable after careful search. Pus wells up from between the first and second dorsal vertebræ. Exposure of the dura reveals a purulent collection extending from the seventh cervical to the eighth dorsal, most abundant at first and second dorsal. At this level the cord is pulpified.

Robert Maguire, *Lancet*, 1888, Vol. 2, P. 9:

History.—Man, aged seventeen. Slept in damp sheets. Onset with pains in lumbar region for several days, very severe. The lower extremities became weak, and later paralyzed. The next day the paralysis ascending, involving the arms. Insufficiency of the sphincters. No shooting pains, no rigidity of spine, no retraction of the head.

Status.—Movements cause slight pain—referred to spine. Severe pain induced by pressure over any part of column. No œdema of back. Paralysis of arms, legs, and trunk with anæsthesia. Died.

Autopsy.—The muscles of the lumbar and cervical regions were infiltrated with pus, especially copious in the lumbar region on the left side. At this point the pus appeared to arise from the arches of the vertebræ. Extensive peridural accumulation of pus from second cervical to cauda. Leptomeninges normal.

Anthony, *Bulletin de Société med. des Hôpitaux, de Paris*, 1892, page 74:

Man, aged twenty-three. In good health; no assignable cause. Acute onset with girdle pains paresis and sensory disturbances in legs; retention of urine; violent pains in the dorsal region of spine, which was very tender from the seventh cervical to the seventh dorsal. High temperature and great constitutional disturbance.

Later complete paralysis of motion and sensation below the umbilicus. Four days after onset, violent pains in left arm and in neck. The sensation over chest diminished, the arms becoming paralyzed.

Autopsy.—The external surface of the dura mater bathed in pus from the third cervical to the lumbar region.

The cord is so softened at the level of the compression as to preclude microscopical examination. The inner surface of the dura and the other spinal membranes are intact. Cultures demonstrated staphylococcus pyogenes aureus.

Meslier (Service of Thibierge), Thèse de Paris, 1894:

History.—Onset February 15. A man, aged nineteen. Following a long march, developed pain in the left leg above the malleoli. There was swelling, redness, and great tenderness over the affected area. Fever, chills, and severe pains. The swelling diminished; the pyrexia, rigors, and sweats continued. Admission March 4. Status: Extreme tenderness along the left tibia, redness, and swelling. Percussion caused agonizing pains. Temperature 40° C.; pulse, 130.

March 6: Intense throbbing pains in the lumbosacral region. Marked tenderness, especially over left sacroiliac junction. The whole spine is rigid and tender, especially between the shoulders; rigidity of neck; retention of urine.

March 8: Delirium and hallucinations.

March 9: Pain in left sacroiliac region disappeared. Severe pain, however in the interscapular region, spontaneous and on pressure extreme rigidity of spine. Death March 13. No paralyses.

Autopsy.—The peridural cellular tissue bathed in pus from third cervical to the cauda. Collections of pus in sacral region on deep incision. Also a perirectal accumulation of pus infiltrating the sheath of the left sciatic nerve. No bone lesion of the sacrum or spine discoverable. Multiple lung infarctions. No focus was demonstrable in the bone, or muscle of the left malleolar region.

NOTE.—The affection of the left leg was at first regarded as an acute osteomyelitis. As the local symptoms subsided, the diagnosis of acute rheumatism was substituted. The case is recorded as one of acute perimengingitis (primary).

Delorme, "Etudes de chirurgie medullaire" (Chipault), Page 369:

Patient, a man. March 18, 1892. Onset with pains in the dorsolumbar region, pains in the knees, great fatigue, pyrexia. Diagnosed, acute rheumatism.

December 15: Paralysis of both lower extremities, anæsthesia to the nipples, girdle sensation. Paralysis of the sphincters. Severe pains in the dorsal region of the spine. Temperature 39° C. Staphylococci demonstrated by culture in the blood. Diagnosis: cord abscess.

December 16: Operation. Laminectomy of the seventh, eighth, ninth, tenth, and eleventh dorsal vertebræ. At the eighth dorsal was a purulent infiltration, beneath which, on the outer surface of the dura, was a fungoid membrane of diphtheritic appearance. This was removed by curettement. Death due to a septic endocardial complication.

Moliere et Perret, *Lyon Médicale*, March 30, 1897:

Man, aged twenty. After exposure to rain, developed pains in lumbosacral region, followed by stiffness of the spine and cramps in the legs. On admission to the Hotel Dieu the pain and rigidity of the whole spine was extreme. Tendency to spasm in the legs; motion, sensation, and reflexes normal. High temperature. Diagnosis spinal reumatism. The pains and rigidity of spine persisted with pyrexia and constitutional symptoms. Death occurred nineteen days after onset. No paralysis.

Autopsy.—Redness and œdema over the spine. In the lumbosacral region, on incising the muscles, pus gushed forth as if under pressure. The surrounding muscular tissues were infiltrated with pus. The external surface of the dura mater was bathed in pus as high as the third cervical. Cord normal. A careful examination of the spine showed no bone disease.

Deléarde, *Gaz. Hebdom. de Med. et de Chirurg.*, 1900, p. 493:

A man, aged twenty-five, in robust health, following an exposure to cold, developed weakness and paræsthesia in the legs, accompanied by severe pains and rigors.

Status on admission: Flaccid paraplegia with preservation of the tendon and abolition of the plantar reflexes. Anæsthesia of the parts below the anterior superior iliac spines. Encircling the upper level of the anæsthesia was a hyperæsthetic band. Retention of urine. The lumbar spine is very tender and painful. Kernig symptoms absent. On the day following, the anæsthesia had ascended to the fourth intercostal space. Sacral decubitus. Pyrexia and septic symptoms.

Autopsy.—The peridural cellular tissue infiltrated with pus. At the site of compression the cord was diffluent, but normal above and below. Streptococci demonstrated microscopically. No other abscess foci; spine normal.

BIBLIOGRAPHY AND CLINICAL TABULATION OF TWENTY-ONE CASES OF ACUTE INFECTIOUS OSTEOMYELITIS OF THE SPINE, WHICH HAVE BEEN RECORDED SINCE THE PUBLICATION OF HAHN'S MONOGRAPH IN 1899, OR WHICH WERE NOT INCLUDED IN THE TABULATIONS PREVIOUS TO THAT PERIOD:

	Reference.	Age.	Sex.	Cause.	Localization.	Neural Complications.	General Complications.	Operation.	Result	Remarks.
1	Swoboda *Wiener klinische Wochenschrift.* No. 4, 1904.	Nursing child.		Mother suffering with acute articular rheumatism.	Cervical region.		Focus in left tibia and cervical abscess.	Abscess incised and drained.	Died.	Staphylococci; tumor formed beneath sternocleido on left side.
2	Suttell, Thése de Lyon, p. 43, 1899.	16	F	Abscess of right breast and left arm following pregnancy.	Lumbar region		Abscess in left lumbar region.	Incised and drained; left side of lumbar spine denuded.	Recovery.	
3	Suttell, *Ibid.* p. 55 (Vincent).	4	M	A fall.	Right transverse process of second lumbar.		Abscess in right lumbar region.	Drained.	Recovered.	Discharged in a plaster jacket.
4	West, Transactions London Pathological Society, Vol. 38, p. 269.	48	M		Body of fourth cervical and disks.	Paralysis of left arm; later legs and right arm.	Onset with paralysis in left arm. (Probably a plexus lesion.)	No operation (a seton).	Died.	Abscess beneath longus colli on right side.
5	Duprat, Thése de Bordeaux, p. 25, 1901.	13	M		First lumbar.		Purulent collections on both sides of first lumbar; second, focus in tibia.	Drained.	Recovered.	Admitted as typhoid fever. Sequestra eliminated, no spinal curvature.
6	Duprat, *Ibid.*	9	F		Fourth dorsal.		A general osteomyelitis. Developed pain and tenderness at fourth dorsal.	Incised.	Recovered.	No sequestra.
7	Warren, *Boston Medical and Surgical Journal*, Vol. 148, p. 503.	23	M		Second and third cervical.	No nervous symptoms.	Torticollis, pain, and tenderness.	Two deep incisions on either side of median line.	Recovered.	
8	Ferrio, Ref. *La Presse Médicale*, January 6, 1900.	19	M		Bodies of seventh cervical and first dorsal.	Rapid onset with paraplegia and anæsthesia ascending to arms.	Painful deglutition; purulent cystitis; trophic disturbances in legs.	None.	Death.	Dura mater is intact. Cord is softened in dorsal lumbar, and lower cervical regions. Infection probably vascular myelitis.
9	Wiesinger, *Deutsche medizinische Wochenschrift*, p. 38, 1901.	21	M		Third and fourth cervical.	Increasing weakness and paræsthesia of legs and arms.	At operation no pus discovered. Eight days later purulent discharge from wound.	Operation: spines of third cervical removed.	Recovered.	Motor power and reflexes returned in legs. Discharged cured.
10	M. Schmidt, *Deutsche Zeitschrift für Chirurgie*, Vol. 58, p. 566.	13	F	Trauma causing focus in right tibia.	Lower cervical.	Sudden paralysis of right arm. Later paresis of left arm and legs. Incontinence.	Development of focus in left hip.	Operation; evacuation of pus in cervical region and spinal canal.	Recovered.	Complete recovery. Paralysis of right arm (Erb type) persisted for three months.
11	Eichel, *Münchener medizinische Wochenschrift*, Vol. 47, p. 1201, 1900.	27	M		Posterior arch of atlas.	No nervous symptoms.	Swelling developed on right side of neck post.	Evacuation of abscess and sequestra.	Recovered.	
12	Wiesinger, *Deutsche medizinische Wochenschrift*, p. 362, 1902.	24	F		Third and fourth dorsal spines and transverse processes.	Slight paresis of legs. Knee-jerk absent.	Evacuation of abscess cavity, including an extradural abscess.	Operation.	Recovered.	Staphylococcus pyogenes aureus demonstrated in blood. Sequestra discharged.
13	Lippmann et Lecéne, *Gas. Hebd. de Med.*, 1901.	16	M	A fall.	Spine and laminæ of third lumbar.	No symptoms. Autopsy: an extradural abscess.	Lumbar abscess incised and drained.	Operation.	Died.	Staphylococcus pyogenes aureus in pure culture; metastatic abscesses in kidneys.
14	Heyking, *St. Petersburgher medizinische Wochenschrift*, p. 60, 1902.	14	M		Sacrum.		Pelvic abscess on rectal examination.	Pus drained through sciatic notch.	Recovered.	Two months later humerus involved; operated; cured.
15	Pilzer, *St. Petersburgher medizinische Wochenschrift*, p. 362, 1902.	12	F		Sacrum.		Whole sacrum infiltrated with pus and removed in toto.	Operation.	Died.	Pus and blood contained staphylococci and streptococci.
16	Weber, *Deutsche medizinische Wochenschrift*, p. 333. 1903.	15	M		Second lumbar.	Extradural collection of pus; no cord symptoms.	Lumbar abscess.	Evacuation of abscess; spines of first, second, and third lumbar removed.	Cured.	Staphylococcus pyogenes aureus. Two weeks after first operation gluteal abscess developed; was drained.
17	Schönwerth, *Münchener medizinische Wochenschrift*, s. 269, 1902.	27	M	Furuncle on right wrist.	First lumbar.	Extradural accumulation of pus, no symptoms.	Pain and tumor in lumbosacral region.	Operation for a perinephritic abscess.	Death.	Diagnosed as a perinephritic abscess.
18	Grisel, *Revue D'Orthopædie*. Nos. 5 and 6, 1903.	9	F		Laminæ of twelfth dorsal and first lumbar.	No cord symptoms.	Lumbosacral tumor on right side.	Incision and drainage.	Recovered.	Streptococcus in pure culture; vertebral deformity; no sequestra.
19	*Ibid*	9	M	Furuncle on left thigh.	Transverse processes of third and fourth lumbar.	No cord symptoms.	Lumbar abscess.	Incised and drained.	Recovered.	No spinal curvature. No sequestra micrococcus Tetragenus.
20	J. R. Hunt.	18	M	A fall.	Sacrum and arch of fifth lumbar.	Compression of cauda equina by extradural abscess.	Painful swelling in left lumbosacral region.	Evacuation of abscess and lamina of fifth lumbar removed.	Recovered.	Atrophy of muscles with R. D. in both legs and left thigh. Skin covered. Slight lateral curvature of spine. Staphylococcus pyogenes aureus.
21	J. R. Hunt.	5	M		Spines and laminæ of sixth and seventh dorsal.	Compression of cord with motor and sensory paralysis.	Painful swelling in upper dorsal region. Staphylococcus pyogenes aureus.	Evacuation of abscess. Spine and laminæ of sixth dorsal removed.	Recovered.	Perfect mobility of spine. Spastic paraparesis still persisting with incontinence of urine.

102 EAST FIFTY-SEVENTH STREET.

OBSERVATIONS UPON THE PROTECTIVE VALUE OF THE INSPECTION OF PUBLIC WOMEN AS CARRIED OUT IN PARIS.*

By FREDERIC GRIFFITH
NEW YORK.
SURGEON, FELLOW OF THE ACADEMY.

FRANCE, which means Paris, sets the fashion in things venereal as in dress. It is probably true that a man visiting Paris will be more likely to seek and fall in temptation of irregular sexual diversions than in any other place. The freedom of speech and action tolerant to the French character, added to the cultivated desire to please, having in view the question of personal gain, is responsible for this, and makes the French woman when she essays the rôle queen of courtezans. It is impossible to tell of the exact number of women that here depend partly or solely upon sexual intercourse as a means of livelihood. The statement that 15,000 females are actively engaged in sexual occupations may be accepted, and as each woman cohabits with from three to ten men in a evening, it is plain that the prostitute of Paris is by no means an idle individual.

As a natural sequence of such promiscuous venery, disease results, and the French capital may be set down as a distributing center of venereal diseases for the rest of the world. The government, alive to this situation, has for centuries tried to lessen the disease-bearing properties of its public women, and that a real interest has been taken in this peculiar people, who are, indeed, no mean factor in the commercial welfare of the country, is shown by the city records. A complete department has been established under the direct supervision of the Prefecture of Police with a chief, a corps of inspectors both police and medical, with their assistants. One-half of a city prison, the Maison St. Lazare, has been set aside as a detention hospital, having over 200 beds, and at the Hotel de Ville, or central municipal government buildings, inspection offices and a dispensary is maintained. Here every actively engaged prostitute in Paris is supposed to come for examination as to the state of her bodily health, having, however, particular attention paid to her sexual apparatus. Every interest of the women is protected by the government supervisors. With the probable thought in mind of future identification by visitors, the lay heads of the departments discourage investigation. As an illustration of the secrecy accorded, I found that a number of the cabmen of the city were unable to drive me to the Maison St. Lazare, neither were they aware of the nature of the work done at that institution. These same individuals, however, would have considered themselves as being worthy of the contempt of their fellows if they could not have driven me in the most direct course to any one of the licensed houses of prostitution now flourishing throughout Paris, the cab drivers throughout the city being the readiest guides to these places.

For a better understanding of the system of municipal control of the city's prostitutes, I will trace the official career of a girl whose morals having become corrupted, becomes careless of her virtue, and bids openly for patronage. She may be arrested by one of the sanitary police for soliciting after midnight upon the streets, or she may excite the attention of one of the regular police officials and be taken for acts of lewdness at any time either upon the streets or about the cafés. For ordinary infringements the girl is taken before an inspector of police, where her age, personal description, and nature of her misdeed is noted; she is then allowed to go. Arrested a second time for a similar offense, she is again quickly freed after official note of her case has been added to the first arraignment. A third arrest brands the offending female as a professional prostitute. Her name is now listed upon the department record at the Hotel de Ville. A small photograph of the girl is taken and glued to a card upon which is written the individual's name, address and date of registration. The card is given to the girl, she is directed to return to the dispensary for medical examination at intervals of fifteen days under penalty of imprisonment of from two to ten days at the Maison St. Lazare, and again freed. Upon the back of the card the dates of her return visits for examination are set down. The card thus becomes the passport for the freedom of the streets of the professional street-walker, or house inmate if she elects to connect herself with one of the ninety odd houses which are to-day officially recognized in the city of Paris. Upon demand of the police or a prospective recipient of her favors, the girl is bound to produce her card for inspection. Failure to produce the registration card or any irregularity in the sequence of the dates subjects the owner to arrest and nominal imprisonment at the detention hospital. In passing it must be observed that, while accepted as a public charge, and with association close to the criminal class, the prostitute is protected within the law as much as are other classes of individuals. The system of espionage is, on the whole, not irksome, and identification not so minute as that of the Bertillon method for avowed criminals.

The life of the solitary prostitute is more in accord with a healthy existence than when herded in a company of from five to thirty-five others in the public house. Besides the competition in immorality, necessarily rife amongst them to attract the attention of visitors, the living of these girls is of the poorest imaginable; as the French kitchen must often not be too closely scrutinized, so here the quarters of the inmates of the cheaper resorts compare with the packing-box retreats of "hop" smokers in a Mott Street Chinaman's joint. Drinking, especially of a light kind of beer known amongst them as "bock" is generally encouraged, to fatten them I suppose, for the tendency of the young French prostitute is to grow scrawny, as it is toward early middle life to become gross.

The French inspection system is to a greater or less extent the pattern for St. Petersburg, Berlin, and Vienna, and there is a growing tendency for cities in our country to look toward it as being probably the best solution of our own municipal social questions. A full exposition therefore of the methods, in so far as they relate to the control of the disease-bearing capabilities of the prostitutes which are carried out there should be of interest. According to Dr. Levy-Bing, chief of staff at the St. Lazare, there are in the neighborhood of 8,000 registered women, all of whom, unless otherwise accounted for by the house visiting inspectors, are assembled and examined in relays upon inspection days. The rapidity with which these examinations are made cannot fail to excite the wonderment of the visitor. Four hundred women having been examined in the space of one hour and a half previous to one of my visits to the inspection office. The feat, for it is no less than one, is accomplished by the aid of two ordinary wooden gynecological examination tables placed facing the light before a large window. The women are ranged in a continuous line of five or six beside the tables. A dozen of the old-fashioned, large-sized, tubular speculæ are at hand, and as fast as used they are dipped in a boiling water-kettle before being returned to the sterilizing solution beside the medical inspector. As the woman settles herself upon the table she receives an observant glance from the doctor. The

*Presented at the Academy, Obstetrics and Gynecology Section, January 28, 1904, and by invitation before the Physicians' Club of Newark, N. J.

speculum is rapidly inserted, exposing the uterine os, and quicker than it takes to tell it, if nothing pathological has been discovered, the woman's place is taken by the next comer. It cannot be gainsayed that a highly developed power of correct snapshot diagnoses can be made by these examiners, as anyone experienced in ordinary surgical or genitourinary dispensary work in a large city hospital must admit.

If the female is discovered to have a rash, or mucous patches in or about the genitalia, she is placed to one side for final disposition after examination of the rest has been completed. She may then be committed to the detention hospital, or if in the judgment of the medical inspector she is not a dangerous disease disseminator she may be allowed to continue her calling while undergoing treatment at the municipal dispensary. As practically all of the prostitutes have perforce chronic vaginitis some allowance is made for this by the examiner. For this reason, and owing to the fact that the French women are expert syringers, gonorrhœal discharge is seldom seen. The haunts of these people being comparatively near to the dispensary, an average case of gonorrhœa can be successfully masked upon inspection day by this means. For, in spite of the manifest benefit to any of them by a stay in St. Lazare, the average French prostitute prefers her life of freedom of the streets to that of enforced confinement at the hospital, and will therefore shrewdly seek to deceive the examiner in every way possible. Microscopical examinations for the detection of the gonococcus are not made, for the reason that practically all of the women are endemic breeders of the germ, and if any concerted attempt at eradication should be made, the hospital facilities would become at that same moment inadequate for the purposes for which it is intended. Syphilis in its grosser manifestations, chancroid, or simple ulcer, with its complications, are therefore the chief conditions sought.

It is especially the older syphilitics who, becoming hardened to their condition, seek by subterfuge to avoid the enforced confinement of months, or even one or two years' time, during which some of them are forced to abide under the restraint of the hospital. To secure a continued freedom I saw a number of females, who by their characteristics and demeanor of action, proved themselves to be undoubtedly professional prostitutes, obtaining treatment in the great skin clinics at the Hospital St. Louis, thus, by medication administered with little or no importance placed upon the source or interdiction of continuance of their calling aside from the usual admonitions they are enabled to continue the life, although certainly not free from risk to their sexual partners.

To show the chance and reality of existence of undetected syphilitic lesions, owing probably to the length of time in the interval between inspections in one public house, harboring some fourteen girls, aging between eighteen and twenty-five years, I discovered two cases showing secondary syphilitic eruptions. In another nearby house, though, in justice to the system, it must be said that this latter place is not regularly listed as a public house upon the city records, although regularly and for years I was told it has continued as such undisturbed, I found a girl of possibly sixteen, though she glibly claimed twenty-one years of life, who presented a well-marked mucous patch at the corner of her mouth. That she, as well as those who had her in charge, thoroughly understood the nature of the condition was shown by the fact that, upon being approached, she momentarily excused herself to return again with the lesion cleverly concealed by the aid of cosmetics.

For the Maison St. Lazare nothing but praise can be said. The medical gentlemen in charge there while keenly alive to the limitations of the value of their work as preventive of venereal disease dissemination to the male sex at the French capital must be rightly proud of the immediate results upon their patients. So marked is the improvement upon the girls that after a few weeks' stay with the quiet, absence of drinking and carousal with enforced regulation of hygiene and proper medication, they become almost unrecognizable in the beneficial physical change which takes place. It becomes apparent to one who has studied the question that there is a distinct advantage to be gained by French prostitutes who continue under the control of the system which has been described. The woman's life is assuredly lengthened many many years beyond the expectation of harlots not subject to such form of municipal control. The woman's existence being considered and her vocation being recognized as legal by the city's authorities, she is not subjected to the same degree of blackmailing with all of its demoralizing effect upon subordinate officials of the city's government as when not so legalized.

The question, however, is the protection and husbanding, not of the female primarily, but of her transient consort. Viewed in this light, the value of the system to the woman in enabling her to continue her career beyond the years of ordinary expectation must be set side by side with the influence which registration carries in the community where it is in force. Again quoting Dr. Levy-Bing who stated to me that there were probably from 16,000 to 24,000 unregistered prostitutes within the city limits of Paris. The influence of the system upon the male population is that of increased security of freedom from attack of disease. Indeed it is considered to be rather a breach of etiquette among the *demi-monde* for a Frenchman to ask his paramour of the occasion to produce her card. And that there is a spirit abroad of afforded guarantee existing against venereal disease in Paris, I have but to cite patients of mine, men about town who have spoken longingly of a desire for a similar condition to be put in effect in American cities.

49 East Sixty-fourth Street.

SOME POINTS ON THE DIAGNOSIS AND DRUG TREATMENT OF PNEUMONIA IN INFANTS AND YOUNG CHILDREN.*

By LOUIS FISCHER M.D.,
NEW YORK.
VISITING PHYSICIAN TO THE WILLARD PARKER AND RIVERSIDE HOSPITAL.

Lobar pneumonia is an acute infectious disease caused by the invasion of the pneumococcus. It is transmittable, therefore our first duty is to isolate. A case of pneumonia should be isolated as strictly as a case of diphtheria. All healthy persons should be excluded, be they family or friends, and it is best to let them know that this disease can be disseminated.

The Diagnosis is frequently a very difficult matter in very young children. The temperature alone is useless as a guide. The ease with which infants and very young children raise a temperature is very well known. For example, a slight gastric derangement will send the temperature to 103°, 104°, 105°. The same holds good when evidences of intestinal autointoxication exist. What is the important diagnostic point? It is to rely upon the disturbance of the normal pulse and respiration ratio. A child in good health has one respiration

*Discussion before the East Side Physicians' Association, March, 1904.

to every four pulse beats. Hence there should be about thirty respirations to every one hundred and twenty pulse beats. When pulmonary disturbance is present this normal ratio of one to four is usually about one to three. There may be fifty to sixty respirations to one hundred and fifty or one hundred and eighty pulse beats. There are several varieties of obscure pneumonia in which the condition is latent, such, for example, is central pneumonia. In these forms of latent pneumonia the pathological process begins in the center of the lung and extends to the periphery. In this form of central pneumonia the physical signs heard on auscultation, percussion, and palpation are useless as a diagnostic aid. Bronchial breathing or even subcrepitant or crepitant râles, cannot be made out until the disease extends from the center to the periphery, a question of several days in some instances.

Infants and very young children rarely cough, and never expectorate the characteristic rusty sputum so common in lobar pneumonia in adults. Therefore this symptom need not be looked for as a diagnostic aid.

Treatment.—Place the child in a room having fresh air and admit all the sunlight possible. The temperature of the room should be between 68° and 72°, never warmer, rather cooler.

Fever Treatment.—There are three methods of eliminating toxins from the body: First, through the bowel; second, through the kidneys, and third, through the skin. In every febrile process there is a slight torpidity of the secretions, hence it is wise to stimulate the emunctories of the body. One drop of tincture of aconite added to one-half teaspoonful of spiritus Mindereri can be given three or four times at intervals of one hour until diaphoresis is produced. A hot mustard foot bath given at the same time will aid the aconite in reducing the temperature. If the fever persists in spite of the aconite, sponging the surface with alcohol and tepid water every half hour will be very grateful and aid in reducing the fever. If we are dealing with a temperature of 105° F. or more, the infant should be watched very closely for twitching or spasm. The temperature at this stage should be reduced by the diaphoretic drugs above mentioned, and instead of cold sponging a cold pack consisting of a sheet wrung out in cold water, should be wrapped around the chest, and should be repeated every half hour until the temperature goes below 103° F. The effect of the cold pack is not only seen in the reduction of the temperature, but some children will fall into a restful sleep. I have always noticed a soothing effect on the nervous system when cool packs, at a temperature of 70° to 80° F., were applied.

Attention to the bowels.—A good dose of castor oil to relieve the intestinal tract is advisable. A very pleasant laxative and one that I use in preference to castor oil, is citrate of magnesia. As citrate of magnesia contains citric acid it not only has a laxative effect, but a diuretic effect as well. It also quenches thirst. I frequently advise the use of acidulated water, made by adding five drops or more of diluted phosphoric or diluted hydrochloric acid to a tumblerful of sweetened water. The same to be given *ad libitum*.

Nutrition.—This is the most important part of the treatment. Unless the strength is supported by proper feeding we cannot expect to have resolution take place and see the baby recover.

The interval of feeding should be prolonged and the food given well diluted. An infant that received eight ounces of milk before it was taken sick should receive during a pneumonia four ounces of milk and four ounces of water. If this is not well borne, milk should be excluded and whey given in its place. Soup or broth or strained gruel may be given. Water should be given freely.

No greater mistake is made than constantly to disturb a child suffering with pneumonia. To give medicine every hour night and day, and keep the child awake, is to retard convalescence. While food may be necessary to stimulate subnormal vitality it should be given with due regard to an infant's requirements, and if the heart's action is good it is poor judgment to awaken a sick child to give food or medicine.

An interesting case, seen recently by me in consultation, was that of a child who vomited during the course of lobar pneumonia. The child was either fed or wakened for medicine every fifteen minutes night and day. Besides this it received a "cough mixture" that contained syrup, which is one of the worst things to pour into a feverish stomach. I stopped the medicine, ordered the infant absolute quiet for at least three hours at a time. The vomiting ceased and the child finally recovered. The child slept quietly after receiving its food or medicine until it was again awakened. I make it a rule not to disturb an infant oftener than every two hours by day, and rarely oftener than every four hours by night. I do not mean to be understood to advocate neglect, especially if nervous symptoms, such as twitching or spasms, are seen during hyperexia, but in an ordinary case of pneumonia in which no severe fever exists rest is as important as fresh air and food.

65 East Ninetieth Street.

PROPHYLAXIS OF PUERPERAL SEPSIS.*

By GEORGE L. BRODHEAD, M.D.,
NEW YORK.

It would seem at the present time, when in our medical schools, and in the medical press, so much emphasis is being laid on the necessity of strict surgical cleanliness in the management of labor, that it should be unnecessary to call attention to the still ever-present danger of puerperal sepsis.

That puerperal sepsis is still a very common disease no one familiar with the existing conditions will question. In hospital practice all observers agree that in the last few years both morbidity and mortality have markedly decreased; but in private practice it is the belief of those most competent to judge, there has been little,if any, diminution in mortality, and no improvement in the statistics of morbidity. Moreover, it is a fact, attested by many authorities, that the statistics of mortality in private practice are extremely unreliable because of the fact that death from sepsis is frequently ascribed to causes other than septic infection. Williams, in his recent textbook of obstetrics, states that it is doubtful whether results are materially better to-day than they were before the introduction of antiseptic methods; and that in England, outside of the lying-in hospitals, sepsis claimed as many, or perhaps more, victims than it did twenty or forty years ago. The same author (Williams) showed conclusively that the vaginal secretion of healthy women is absolutely free from pyogenic cocci, but that bacteria are present upon the hymen and labia minora in most cases. If, then, the vagina is free from pathological bacteria, the cause of sepsis must necessarily be the introduction of septic material from without. We cannot doubt that, as a rule, the germs are carried in on the examining finger,

*Paper read before the Hospital Graduates' Club, March 24, 1904.

and thus we find that the internal or vaginal examination during labor is directly responsible not only for a large number of deaths, but for a vast amount of suffering and years of invalidism as well. With all possible precautions, there is always a small element of risk in making a vaginal examination in labor, and the question naturally arises: "Is it necessary or advisable to make internal examinations during labor?"

In answer to this let us consider for a moment the objects to be attained in making such an examination. We desire to inform ourselves as to (1) the presentation and engagement; (2) the position; (3) the degree of dilation; and (4) the possible presence of a prolapsed cord. The diagnosis of presentation, engagement, and position can almost invariably be made out by careful external examination; and, therefore, it is unnecessary in the majority of cases to use vaginal touch. The amount of information which can be obtained from a painstaking, thorough abdominal examination is really wonderful. I believe that in the teaching of ante-partum and intrapartum diagnosis by external manipulation lies one of our greatest safeguards against puerperal infection. I am convinced that many lives are lost each year from internal examinations which were absolutely unnecessary; and that, taken as a whole, internal examinations are productive of far more harm than good. Labor is a physiological process, and interference of any kind is in many cases wholly unwarranted. As to the amount of dilation present, we should be guided, I think, largely by the character of the pains, their frequency, the duration of labor, and the parity of the patient; and dilation must certainly be taken into account if the patient is to be left without attendance for a number of hours. But given the case of a primipara, for example, in which we know by external examination that the presentation and position are normal, when the pains have been going on for a short time only, and the membranes are intact, the fetal heart being strong and regular, it is unnecessary to examine for dilation—for unless one is to be prevented from seeing the patient for many hours there will usually be ample time in which to return. In multiparæ, when the pains are strong and frequent, it may be necessary to examine; for, possibly, it will be unsafe to leave the house. If however, the physician is to remain with the patient, or is ready at any time to respond to the call, internal examination to determine the amount of dilation is unnecessary. Prolapsed cord is a rare occurrence; and in many cases the complication cannot occur, for the reason that the head of the child is firmly engaged in the pelvic brim. If, on the other hand, the head is freely movable above the brim, internal examination should be made immediately after rupture of the membranes; for, under these circumstances, the cord may have prolapsed. Enough has been said, I think, to show that internal examinations are undoubtedly made far more often than they should be; and in my own practice I have demonstrated over and over again that labor can be conducted successfully with no vaginal examination whatever. Even when labor is prolonged, the number of examinations can be limited to but very few. In tenement practice, the rule of infrequent examinations (if indeed any are necessary), is especially applicable, for obvious reasons. To emphasize the point which I desire particularly to bring out, let me make an earnest plea for careful ante-partum examination of our patients, to the end that at the time of labor internal examinations will be unnecessary, or at least they will be made only in the presence of strong indications.

If internal examination is necessary, the best method of sterilization of the hands and vulva is that advocated by Stewart of New York in the MEDICAL RECORD of January 30, 1904. In my practice I use for the vulva a solution consisting of chloride of lime, one teaspoonful, and acetic acid (U. S. P.), two teaspoonfuls, to the quart. For the hands, after the cleansing with soap, water, and powdered pumice stone, I use chloride of lime, two teaspoonfuls; acetic acid, four teaspoonfuls, and water to make one quart. The hands are immersed for five minutes in this solution, they are then rinsed off in a one-per-cent. lysol solution, after which rubber gloves are worn. By use of the method above mentioned, the danger of infection is exceedingly small. For further details of the method I would refer to Dr. Stewart's paper.

110 WEST FIFTY-SEVENTH STREET.

PRELIMINARY NOTES ON TRANSILLUMINATION OF THE STOMACH WITH FLUORESCEIN.*

BY H. W. LINCOLN, M.D.,
BROOKLYN.

CONSULTANT IN GASTROINTESTINAL DISEASES TO THE HOWARD ORPHAN ASYLUM; ATTENDING PHYSICIAN TO THE BUSHWICK CENTRAL HOSPITAL, ETC.

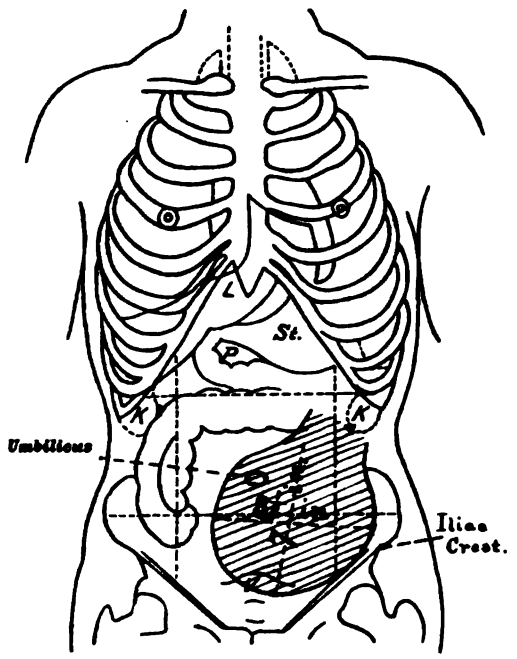
TRANSILLUMINATION of the stomach as a diagnostic method has been practised for some years since its inauguration by Einhorn.

Transillumination of this organ, employing a solution of fluorescein as a translucent medium has been done, so far as I am informed, only since October, 1903, by R. Coleman Kemp of New York. Before using this drug in the human subject it was most exhaustively experimented with upon the lower animals by injection, both subcutaneous and intravascular, and proven to be absolutely harmless. A solution of the strength of 10 grs. to the ounce was pronounced non-irritant in the stomach. The description of the drug is brief. It is a naphthalin product, is a red powder, gives a greenish yellow fluorescence, and is phthalic anhydrid, 5 parts resorcin, 7 parts heated to 200°. The solution we use at a distance shows a very beautiful green ring $\frac{1}{16}$ to $\frac{1}{8}$-inch thick at its thickest. For convenience, I have the powder made into compressed tablets. Used in above ¼-gr. doses it loses its illuminating properties to some extent, but if 1 gr. or more be used it becomes dense and like an aniline dye, such as congo red. Acidity lessens its power, as determined by Kemp, who tried it in varying strengths of HCl in the stomach. The previous administration of quinine increases translucency, as also does the co-administration of glycerin. For much of the above I am most gratefully indebted to Dr. Kemp.

As is well known, there are many cases in which we would like to determine beyond any question just where the stomach lies and also whether it is enlarged or dilated (there is, to my mind, a great difference between megalogastria and dilatation). In the typical hypochondriac who is below weight, with thin abdominal walls, neurasthenia in every line, etc., we can get a fair outline of the lower curvature at least, together with epigastric impulse over a large area (I recently examined one in which the phenomenon could be *seen* for six inches several yards away from the patient), a history of mucous colitis and so on. In this class the lamp with simi

*Read with demonstration before the Kings County Medical Society, Section on General Medicine, March 1904.

water in the stomach will be satisfactory, but there are many others decidedly atypical with regard to muscular development in which all the usual methods fail to tell us positively the exact location and size of the stomach. Could we place a stopcock at the pylorus, filling the organ with either water or air might help us out, but we cannot. The splashing sound is not sufficiently precise. In the method we have one free from objection either to patient or the profession, accurate, inexpensive, easy of application for both patient and physician, and, what is more important, one which can be practised anywhere. The lamp which I use is one which I had made after my own ideas some four or five years ago. It consists of a small capsule which has the light in one end, and is connected to the battery by fine copper wires enclosed in a very fine rubber tube, little larger than the ordinary match. An illustration of this lamp was published in the *New York Medical Journal* at the time it was made. Its very great advantage



is that the patient does not need to become accustomed to the tube, the case to be demonstrated being one that bears that instrument badly. I believe it better in most instances to allow the individual to introduce the light himself as, unlike the stomach tube, the lamp will go down very easily, and after that there seems to be no irritation from the little cable, and no nausea. I might also remark that it is better to introduce the lamp before the solution, so that should there by any chance be any trouble, the fluorescein will not be vomited. Besides, there is positively less irritability with the stomach entirely empty. This may seem a small matter, but experience will prove its value. The best time to examine is at night, the patient having fasted since noon. The heat thrown out by the light is minimum and of no account, as the lamp is, of course, immersed in the solution. Method: Give the patient 10 or more grs. of quinine during the day of examination or the day previous. Introduce the lamp. Have the patient drink a glass of water into which has been dissolved 30 to 40 grs. of sodium bicarbonate, to render the gastric contents alkaline. Allow another glass of water to be taken, into which has been placed 1/8-gr. of fluorescein, 1 drachm of glycerin, and 20 or more grs. of sodium bicarbonate. The abdomen being bared, conduct the patient into the dark room or, if at night, simply turn out the lights.

The patient was referred to me last October, having suffered from two severe hemorrhages and shock. Ulcer was diagnosed and a hurry call brought the patient to the Bushwick Central Hospital, where, after three weeks' treatment, she recovered without surgical interference. Since leaving the institution there has been marked general improvement, together with some gain in flesh. The accompanying illustration shows correctly what I found as marked upon the abdomen with the light *in situ*, and measured after leaving the dark room. Diagnosis, megalogastria and gastroptosis. It will be seen that the stomach lies upon the left iliac crest and also extends to the right to beyond the umbilicus. The navel seems a very unfixed point on the line between the ensiform and the symphysis.

I have successfully examined persons of all weights up to 175 pounds, and with all thicknesses of abdominal wall. This could be done by no other method.

Growths lying upon the anterior gastric wall, or anything lying between the stomach territory and the observer, will show as a dark spot, as in one case examined a plugged transverse colon stood out beautifully.

Since presenting the above I had opportunity of examining a negress weighing 150 pounds, whose abdomen was heavy, in whom I had had administered quinine in minute doses for forty-eight hours previously. I was very anxious to compare negro and white. I obtained a very good picture; not as I had hoped, that perhaps the pigmentation might to a minute degree enhance the translucent value of the fluorescein, but yet a shadow which well paid me, and permitted seeing and measuring beyond any doubt exactly where the stomach lay. The exposure took place before the staff of the Bushwick Hospital.

113 HANCOCK STREET, BROOKLYN.

SUPPLEMENTARY NOTE ON A CASE OF TYPHOID SPINE.

BY LEONARD W. ELY, M.D.,
ORTHOPEDIC SURGEON TO THE ROOSEVELT HOSPITAL DISPENSARY.

IN the MEDICAL RECORD of December 20, 1902, I reported a case of typhoid spine. At that time I said: "The patient now goes about wearing his brace. He can walk a moderate distance and attend to the lighter duties of his practice." A few further notes may be of interest.

Soon after the report was made the patient undertook some active work and began to leave off his brace about the house during the evening. The pain in his back became worse and the lateral curvature more pronounced, and on January 1, 1903, he applied to Dr. Gibney for treatment. The treatment consisted of the thermocautery two or three times weekly, and of the brace, which was now worn during the entire twenty-four hours, and it was continued for about six weeks. At the end of that time the cautery was stopped, and after a month or two longer, as the pain and discomfort decreased, the brace was left off—at first during the night, then gradually during the day, until it was finally discarded about May 1. After that date, with the exception of some weakness, the only symptom remaining consisted of occasional attacks of cramp-like pain occurring at increasing intervals, and ceasing altogether after two or three months,

leaving the spine finally practically normal. These cramp-like attacks of pain might be described as a "catch," and were followed by a return of the lateral curvature to the side opposite the pain, this lateral curvature gradually wearing away and reappearing with the next attack.

The whole duration of the disease was about eighteen months, which agrees well with the accounts of the cases heretofore published.

An examination by Dr. Gibney, several months ago, showed that the only visible remnant of the affection was a slight lateral curvature.

451 West End Avenue.

Statistics of the Use of Diphtheria Antitoxin.—The Bulletin of the Chicago Health Department says that between October 5, 1895—date of first case treated—and December 31, 1903, the antitoxin administrators of the department treated 7,435 cases of bacterially-verified diphtheria, of which number 479 died—a mortality rate of 6.44 per cent. The average mortality without antitoxin still remains about 35 per cent. That the value of antitoxin depends upon its early administration is shown by the following: Of the total 7,435 cases, 586 were treated on the first day of the disease, with 2 deaths—mortality rate, 0.34 per cent. Of 1,913 treated on the second day, 28 died—mortality rate, 1.46 per cent. Of 2,624 treated on the third day, 85 died—mortality rate, 3.24 per cent. Of 1,374 treated on the fourth day, 148 died—mortality rate, 10.8 per cent. Of 936 first treated later than the fourth day, 216 died—mortality rate, 23.1 per cent.

The Effect of the Saline Mineral Waters on Metabolism.—Dapper, who has subjected the properties of certain saline waters to exhaustive clinical studies, comes to the conclusion that these waters have great value in modifying the formation of hydrochloric acid in gastric disorders. In many cases of catarrhal and other conditions a pronounced and permanent increase in hydrochloric acid formation is produced. In disorders associated with hyperacidity, especially in nervous dyspepsia, the judicious use of the waters is followed by a reduction of the acidity and improvement in the symptoms. The treatment does not require adherence to a rigid diet, indeed strictness in this regard is often undesirable. Especially the use of fats in considerable quantities, of raw fruit, of salad, vinegar, etc., is in many cases beneficial rather than the reverse. Large amounts of saline waters do not impair the assimilation of fats or other foods, and they may safely be administered even in the treatment of obesity. Uric acid excretion is slightly increased, so that these waters are entitled to consideration in the treatment of uric acid retention.—*Von Noorden's klinische Abhandlungen*, No. 5, 1904.

Suggested Physical Examination in Cases of Sciatica.—In an article on referred pains, mostly gouty in their origin, W. Bruce advises the following procedure in sciatica to determine whether or not the hip-joint is affected in such cases: (1) Find out if there be a limp, and in which leg. (2) Place the patient, in his usual clothes, on a firm couch, lying on his back. Flex the affected leg at the knee and then the thigh on the body; evert and invert the leg at the hip-joint; try Thomson's test by extension of the affected leg, while the other leg is fully flexed, and note the results as to extent of movement and pain in each case compared with normal conditions. (3) Expose the hips, placing the patient on his face, noting (*a*) wasting (or not) of the glutei; (*b*) if any obliteration of the folds of the nates; (*c*) any fulness over the capsule; (*d*) any heat over the same; (*e*) any tenderness on deep pressure over the capsule; (*f*) any similar tenderness, and what amount, at the sciatica notch, or in the course of the sciatica nerve. But be very careful to make sure that the patient does not mislead you, because where he has the painful feelings, there he is sure is the seat of the disease.—*Scottish Medical and Surgical Journal.*

The Formation and Resolution of Peritoneal Adhesions and Exudates.—H. J. Wetherell advances the following propositions: (1) Peritoneal adhesions and exudates are essentially conservative in their purpose and effect. (2) With certain very rare exceptions, when the source of irritation or infection which causes them is removed and the necessity for their further existence is past, they will be taken up and disposed of almost or quite completely. (3) Tympanites, through increasing the intraabdominal pressure without peristalsis, and even so-called intestinal paralysis are also means to the same conservative end. (4) We should be most reluctant to antagonize any of these conservative agencies during the acute stage of the disease by untimely operation, or the administration of food or cathartics. (5) Ordinarily, an interval operation will be required for the removal of the source of the infection in order to restore the patient to health and insure immunity from relapses, and such an operation in skilled hands is many times safer than taking the chances of leaving it alone. They are quite uniformly successful and attended with an extremely low mortality.—*Colorado Medical Journal.*

The Implantation of Carcinomatous Tissue into the Brain of Experiment Animals.—Wagner describes experiments undertaken to test the correctness of the assertions of Adamkiewicz in regard to cancroin, the remedy against carcinoma devised by the latter. One of the fundamental principles of the theory underlying the application of the remedy consists in the assumption of a directly toxic principle excreted by the carcinomatous cells, and Adamkiewicz claimed to have proved this by experimental work on rabbits. Animals that had bits of carcinomatous tissue implanted into their brains died within twenty-four hours, while others inoculated with sarcoma or other tumors survived. The author repeated these experiments with several modifications and was able to show that death following the implantation of carcinomatous material is due solely to the associated bacteria present and that sterile portions of cancerous growths are just as well borne by the tissues as other benign tumors or sarcoma. On the other hand, benign tumors when infected with bacteria obtained from the non-sterile carcinomata caused death in exactly the same way as these did. These observations demolish the experimental groundwork of Adamkiewicz's theory just as clinical observations have deprived it of all claim to therapeutic effectiveness.—*Wiener klinische Wochenschrift*, March 24, 1904.

The Pretyphoid Fever State.—Robert D. Rudolf thinks that this term is properly applied to a state of health, or rather ill health, which occasionally precedes, for perhaps some weeks, the onset of enteric fever. The patient complains of indefinite symptoms, malaise, with want of appetite, dyspepsia and disturbances of the bowels, usually in the direction of constipation, often attended by some irregular fever, and at last a regular attack of typhoid fever sets in. The author thinks that this state precedes typhoid fever sufficiently often to receive special notice. This condition of lowered state of health associated with gastrointestinal disturbances may predispose to typhoid infection by lowering the local or general resisting power of the individual. It may be due perhaps to the presence of typhoid bacilli in the intestine setting up an irritation for weeks before the true typhoid. There are many authorities for believing that irritation of the intestine predisposes to the severer intestinal infections. Sir Taylor writes, "It is a notorious fact in all our military campaigns, whether in South Africa or in the Nile Valley or in Northern India, that those soldiers, especially the young ones, who suffered from catarrhal affections of the bowels, were more rapidly attacked by enteric fever than were their comrades who were in perfect health."—*Canada Lancet.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., 51, FIFTH AVENUE.

New York, April 23, 1904.

DISEASE OF THE HEART DUE TO OVER-INDULGENCE IN ALCOHOLIC DRINKS.

DR. W. HALE WHITE, London, England, calls attention to the fact that there is a form of disease of the heart which has attracted very little notice in Great Britain, but which is often described in German medical writings, namely, that associated with an over-indulgence in alcoholic drinks. This condition was observed in the form of dilatation and hypertrophy of the heart and was first named "Tubingen heart." It was soon discovered, however, that the same form of heart disease occurred in Munich and in many other places in which the consumption of beer was excessive. Osler says that Strümpell, at his Erlangen clinic, told him that the condition was very common there among those who worked in breweries. Krehl, in "Nothnagel's Specielle Pathologie und Therapie," devotes a separate chapter to the heart disease which follows excessive indulgence in alcoholic drinks, and while he fully admits the existence of what he calls the "Beer heart," he is somewhat doubtful whether the same condition follows excessive drinking of wine, but with regard to its following spirit drinking he says that at any rate it must be very rare, and he himself knows of no case.

Dr. Hale White thinks that Krehl shows a commendable caution in heading this chapter "Heart Disease due to Over-Indulgence in Alcoholic Drinks," for the reason that the condition is so well known where beer is drunk, and rare where other forms of alcohol are taken to excess, this fact giving rise to a very strong doubt as to whether it is the alcohol that is the cause of the trouble. The writer states that in cirrhosis of the liver and peripheral neuritis, the consumption of alcohol is not co-extensive with the prevalence of the disease, and we do not know for certain which is the offending constituent of the alcoholic drink, so that it is much more accurate to describe the affection as due to alcoholic drinks rather than to alcohol.

Again, because the condition is so much more common among those who drink German beer than among those who drink other alcoholic drinks it has been suggested that it may be due to the carbohydrates in German beer; but Dr. White remarks that if this be so it must be some special form of carbohydrate, for carbohydrates in general do not lead to cardiac hypertrophy and dilatation; for if they did this heart trouble would be often seen among Irish peasants, who live upon potatoes. The suggestion has also been made that the large quantity of fluid drunk by these beer drinkers is the cause of the hypertrophy and dilatation, but the writer is of the opinion that the force of this view is negatived when it is considered that the body so quickly gets rid of an excess of fluid in the vessels that we have no certain proof that the total amount in the vessels at any time is much above normal; and that, further, the work of the heart is the resultant of the quantity of blood and the rate of the flow, and if the quantity be increased it may be that the rate of flow is diminished —for a rapid pulse does not necessarily mean a rapid flow. It has also been said that the salts in the beer may cause the trouble; but of this, Dr. White says there is no proof, nor does he deem it likely that Bauer's suggestion placing the cause of the hypertrophy on increased peripheral resistance due to alcohol is correct, for the pulse is always low tension. Dr. White likewise scouts the supposition that this condition is due to alcoholic vagal neuritis, a theory advanced by some writers, although not by German authors, and concludes that we do not know precisely the cause of the disease characterized by cardiac dilatation and hypertrophy, and known as "Tubingen heart," "Munich heart," or "Beer heart."

The writer then describes five cases which were under his immediate care in Gray's Hospital, and draws certain deductions from these, and from the autopsies performed upon them. The post-mortem appearances were as follows: In none of them was there any renal or valvular disease to account for the cardiac hypertrophy. In the first case this reached twenty-two ounces, and there was fatty degeneration of the heart, but this is to be ascribed to the alcohol, for the coronary arteries were perfectly healthy. The liver was extremely fatty. In the second case it might be urged that the atheroma was not sufficient to call for any particular comment from the demonstrator of morbid anatomy. To the naked eye, at any rate, there were none of the fatty, fibroid and degenerative conditions characteristic of disease of the coronary arteries, and during life the symptoms were so striking that the patient was believed to be suffering from an alcoholic heart, and after death this organ was found to weigh twenty ounces. Unfortunately no mention is made in these two cases as to whether the right side was hypertrophied as well as the left, but in the third case the heart was uniformly enlarged, and both the symptoms during life and the conditions after death showed a typical alcohol heart. The fourth case showed at the post-mortem a typical alcohol heart.

The final conclusions of Dr. White, drawn from his own cases and from literature on the subject, is that at present we know of no histological changes which are characteristic of alcoholic disease of the heart.

CONGENITAL TUBERCULOSIS.

THAT the new-born child may be the victim of tuberculosis, acquired during intrauterine existence, has been indubitably demonstrated. It is believed that the infection may be transmitted from either parent, but this must take place in the large majority of instances from the mother. While the number of cases of undoubted congenital tuberculosis on record is not large, this fact may be due in part to difficulties in demonstration and in part to want of careful and thorough examination. Placental and

fetal tuberculosis are not uncommon in cows. It has been thought that the intact syncytial layer of the chorion forms a secure barrier to the passage of microorganisms from the maternal to the fetal blood, but this may not be invariably so. A case bearing upon this subject has recently been reported by Drs. A. S. Warthin and D. M. Cowie (*Journal of Infectious Diseases*, Vol. I, No. 1), who also analyze the recorded cases. The patient was a woman, twenty-seven years old, who died in the seventh month of pregnancy, after giving birth to a dead fœtus. Port-mortem examination disclosed in the mother chronic primary tuberculosis of the kidneys, subacute miliary tuberculosis of the lungs, the liver and the spleen, tuberculous cystitis, tuberculosis of a true corpus luteum and tuberculous thrombosis of the decidua; in the fœtus the presence of tubercle-bacilli and agglutination thrombosis in the blood, without histological alterations; and in the placenta tuberculosis of the chorionic villi and tuberculous thrombi in the intervillous spaces and the chorionic vessels. From the evidence afforded by this case and from a study of the literature of the subject, the conclusion is expressed that when tubercle-bacilli (miliary tuberculosis or chronic tuberculosis) or other microorganisms gain entrance into the maternal blood during pregnancy the conditions of the circulation in the placental and uterine sinuses favor the collection of the bacteria in those situations. If the bacilli are capable of multiplication, the first step in the development of tuberculosis of the placenta appears to be thrombosis due to agglutination and coagulation of the maternal blood in the intervillous spaces. The formation of such thrombi around the multiplying bacilli may, to some degree, be effective in inhibiting or restricting their growth. The syncytium appears to possess a certain degree of resistance to tubercle-bacilli, the tuberculous thrombus in many cases being attached to an apparently normal syncytium, and occasionally the latter may be found extending over the thrombus. The question of the passage of tubercle-bacilli through an apparently normal syncytium still remains open. If the syncytial covering undergo destruction, the stroma of the chorionic villi may become involved in the tuberculous process, either directly or by extension from a tuberculous thrombus. The syncytium of the normal placenta is not intact throughout, processes of decay and growth taking place in the chorionic villi from the earliest stages of pregnancy. In the later months the placenta is a senile organ, presenting in many places an atrophic or necrotic syncytium (infarction), and through such damaged areas microorganisms may pass. The deposit of fibrin, found so frequently over damaged areas, may tend to prevent the passage of the bacteria. Tubercle-bacilli may be found free in the reticular spaces and blood-vessels of the chorionic villi without the histological changes of tuberculosis. The fetal blood may contain large numbers of tubercle-bacilli without other changes than the presence of agglutination thrombi, and inoculation demonstrates that these bacilli have retained their virulence. It may, therefore, be assumed that the fetal tissues are relatively immune to the effects of the tubercle-bacillus. Admitting such immunity, it is possible that living tubercle-bacilli may be present in the fœtus and the new-born child without exciting histological changes; and developing some time after birth, they may then give rise to characteristic tuberculous lesions. A true latent congenital tuberculosis is, therefore, both possible and probable, but additional investigation is necessary to establish the frequency of such an occurrence. The commonly accepted dicta regarding congenital tuberculosis are probably extreme. It is not at all unlikely that this condition is of much more common occurrence than is generally appreciated.

RECOVERY AFTER PROTRACTED SUPPRESSION OF URINE.

SUPPRESSION of urine of any considerable duration is so generally fatal that the report by Dr. George Heaton (*Birmingham Medical Review*, February, 1904, p. 94), of a case in which recovery ensued after such a condition had existed for more than eight days in consequence of impaction of a calculus in the ureter, would seem to be deserving of special note. The patient was a blacksmith, forty years old, who had previously had attacks of pain in the loins and the abdomen—in the last three months before coming under observation having passed by the urethra blood and twenty small red-colored calculi—and for a few weeks had noticed that his abdomen was rapidly increasing in size. He was, early one morning, awakened by severe pain in the epigastrium and across the loins, with a strong desire to pass urine, but without being able to do so. The pain moderated in a short while, and also the desire for micturition. On examination on the fifth day, the abdomen was found greatly distended, but free from tenderness. Consciousness was preserved, and the mental state was unaffected. A catheter was without difficulty introduced into the bladder, but no urine escaped. These conditions persisted for two days more, when, a diagnosis having been made of obstructive suppression of urine, probably from impacted calculi in the kidney or the ureter, the left kidney was exposed through a lumbar incision and found atrophied. The ureter could not be seen or felt, nor any swelling in its usual course. The upper portion of the wound was closed and drainage provided for from the lower angle. There was a good deal of vomiting after the operation, but no urine was passed until the ninth day, when the discharge began suddenly, eight or ten ounces being passed at a time at frequent intervals. A total of 173 ounces was voided in the first twenty-four hours, 178 in the second, 136 in the third, and 126 in the fourth. Thereafter the quantity gradually diminished, although it continued to be from fifty to eighty ounces in the day. The urine at first passed contained a little blood and a trace of albumin, the former, however, soon disappearing, but the latter persisting. Some two months later three small uric-acid calculi were passed.

The case is interesting—apart from the fact that recovery ensued after anuria of such long standing and in the sequence of an operation probably not affecting directly the obstructed organ—on account of the absence of symptoms of uræmia. The thought, therefore, suggests itself that these symptoms, when they occur, are not due alone to the suppression of urine, but that other special factors may be necessary for their development.

PROFESSOR EHRLICH'S VISIT TO AMERICA.

PROFESSOR EHRLICH'S recent visit to Baltimore for the purpose of delivering the first series of Herter lectures was the means of forging another link in the bond of interest between the physicians of Germany and the United States. The high position which this gentleman occupies as the director of the Institute for Experimental Therapeutics in Frankfort, and his well-recognized eminence as a brilliant scientific investigator, served as a means of attracting a large gathering of interested auditors to McCoy Hall, at Johns Hopkins University. The technical difficulties of the subject, and the fact that the lecturer spoke in German, necessitated the closest attention, but the hearty applause which greeted the speaker at the beginning and the end of each session, afforded substantial proof of the impression he had made. During the course of his lectures on "Immunity," he frequently alluded to the attainments of American observers in this field of research. And these were not idle compliments, such as might be bestowed by a guest on his hosts, for the impression one gained from seeing and hearing Professor Ehrlich, revealed him as a sincere and earnest man, not given to flattery or wasting time on idle compliments.

A pleasant feature occurred after the last lecture. At its conclusion Dr. Wm. H. Welch spoke of the munificence of Dr. and Mrs. Herter in affording to the American medical world this opportunity of hearing foreign authorities lecture in that particular field where they had attained their reputation. Then, turning to Professor Ehrlich, he addressed the latter in German, thanking him for his kindly efforts and labors to make these lectures a success, and assuring him of the high regard which American workers entertained for his scientific attainments. This elicited from Professor Ehrlich a reply couched in the most sincere and friendly terms, in which he alluded to the constantly increasing interest and appreciation which Germany is manifesting in American medical research. He also expressed open admiration for the zeal and earnestness which animated Americans to extend their search for knowledge beyond the confines of their own country. The example set by Dr. Herter led him to hope that ere long steps might be taken in Germany toward establishing a similar institution, so that foreign investigators could be invited, their ideas be interchanged in certain fields of endeavor with which their names had become intimately associated. In concluding, he expressed himself as not only pleased with his visit, but as bearing away with him new ideas and aspirations, that he came to instruct and was instructed, and in going away he felt that he did not want to say good-bye, but merely "*auf wiedersehen.*"

The receptions given him in Chicago, Ann Arbor, and especially in New York, have also abundantly shown how much his brilliant labors in his department have been appreciated by his *confrères* in America. The banquet tendered him by the German Medical Society of this city was one of the most cordial of its kind with which any previous medical visitor has been honored. The eloquent speeches by Adler, Jacobi, Meltzer, Dunham, Breitenfeld, and the response of Ehrlich elicited an enthusiastic appreciation seldom vouchsafed in a similar scientific assembly. Ehrlich, with a generosity that proved the true merit in himself, repeated his high estimate of research work in America and thus gracefully reciprocated similar sentiments expressed to his own country. In no surer way can science prove its broader aims and its widening cosmopolitanism.

THE PROBLEM OF THE CRIMINAL.

The criminal has always been an object of the greatest solicitude, and is more so to-day than ever before. The means taken to reform him are many and varied and differ considerably in all countries. In Great Britain the principle has been followed of deterring vicious persons from pursuing their evil path by punishing them severely when caught breaking the law. This system, however, has not been successful, but has probably more frequently had the effect of rendering those thus treated more confirmed in their vicious ways. The mode in vogue here for endeavoring to reclaim criminals has been chiefly conceived on an entirely opposite plan to that of Great Britain. Reformatories and institutions of a like nature have flourished, but men who have had experience with the prison population in the United States declare that, as a rule, treating criminals by kindness does not turn them from following the path which they have chosen or fallen into. At the annual meeting of the Association of Executive Health Officers of Ontario, held on the 9th and 10th of September, 1903, Dr. C. K. Clarke of Kingston, Medical Superintendent of Rockwood Hospital for Insane, read a paper on the care and treatment of the criminal. His classification is as follows: (1) The criminal insane; (2) Moral imbeciles; (3) Instinctive criminals; (4) Occasional criminals; (5) Habitual and professional criminals; (6) Accidental criminals.

The writer defines the moral imbecile as one who is devoid of moral qualities, and drops into criminal acts without any exhibition of viciousness or sense of responsibility. The instinctive criminal differs from the moral imbecile in that he is vicious from the outset. He is not only mentally but physically abnormal, and his depravity is absolutely beyond reach. The occasional criminal is one whose weakness is his chief characteristic. The accidental criminal, or criminal by passion, is, in the majority of instances, a normally constituted person, who, stung by some great injustice or wrong, takes the law into his own hands, and in a moment of passion commits a crime.

Dr. Clarke protests against the British system of punishing the crime alone, and is inclined to agree with Havelock Ellis, who said: "The key to the failure of the prison, and a chief clue to its reform, lies in the system of administering definite and predetermined sentences by judges, who, being ignorant of the nature of the individual before them, and therefore of the effect of the sentence upon him, and of its justice, are really incompetent to judge." The first step in the solution of the problem should be the development of the indeterminate sentence.

The writer does not believe that crime is invariably the outcome of disease. He is also of the opinion that when the tide of emigration turns to Canada, as it is now doing from Europe, more will be known concerning the criminal than is the case at present. He thinks that Canada should take warning by the experience of the United States, which has resulted in such a serious condition of things in this country, and advises that a far more rigid system of inspection should be adopted. In a few words, Dr. Clarke is strongly of the view that the alien degenerate should be excluded from Canada by all possible means.

Hemorrhagic Septicæmia in Animals in the Philippine Islands.

Several cases of the above condition have occurred in the Philippine Islands, chiefly among carabaos, and have been reported on by Drs. Wooley and Jobling of the Government Biological Laboratory.

The investigators say that in summarizing the main clinical features of these cases three fairly well differentiated types have been observed—one, intensely acute, in which the animals died within a few hours after the onset of symptoms; one less acute in which the animals suffered chiefly from weakness in the limbs, and more especially in the hind ones; during the course of this form of the disease the appetite was little or not at all affected. Lastly, one in which the course was prolonged, accompanied by great weakness and emaciation and occasionally by suppuration. These, however, are not distinctly defined types, for rarely, say the authors, does the disease affect the animals in the same way, except in the acute form, in which the course is so rapid that there is little time to observe symptoms.

The pathological types are as indefinitely defined as the clinical types. In a general way, there is a pulmonary type in which the lesions resemble those of bronchopneumonia, sometimes with abscess formation, and with or without pleuritis. Combined with these changes there may be marked changes in the interlobular tissues, with the formation of fibrous bands and with emphysema. Another type is the rapidly septicæmic form, in which there are few macroscopic changes in the organs beyond incipient parenchymatous degenerations. The third type is a glandular and suppurative one, which terminates in a general infection. In all these forms there have been more or less widespread hemorrhagic lesions combined with gelatinous œdemas. This last-named condition was especially frequent about the base of the heart, and in some cases it was the only macroscopic lesion. The clinical cases given above agree in many points with those described in the literature of the affection, but in many details they do not. Wide variation clinically and pathologically seems to be one of the most common features of the disease caused by B. plurisepticus.

From a summary of the facts given in the literature, it may be concluded that the animals attacked are of all ages, the onset is usually sudden, the course is rapid and death occurs in from 85 to 98 per cent. of the cases. In the less rapid forms of the disease the symptoms may be refusal of food, cessation of rumination, and lactation. The initial rise of temperature may be followed by a drop to normal or subnormal. The respirations may be rapid or labored, bloody material may be discharged from the nostrils, bowels, or bladder, and noncrepitant swellings may occur on face, neck, or about the back and ankles. In the outbreak, studied by Drs. Wooley and Jobling, the characters of the microbe have been as follows: Short bacilli with rounded ends, polar staining, occasionally encapsulated, and non-motile; non-liquefying, non-Gram staining, growing invisibly on potato, not producing gas, not coagulating milk or reducing litmus, producing indol and nitrites, and not forming spores. It is an organism which corresponds closely with the bacilli of hemorrhagic septicæmia of Hueppe, and especially with that member of the group called B. boviseptícus (Kruse), B. bovisepticum (Kruse-Migula), B. der buffelseuche (Oreste-Armanni), etc. The chief differences between the present bacillus and the ones described in the literature are its indol production, which is invariable, and its invisible growth on potato, which also appears constant.

There has been no evidence that the disease in the Philippine Islands is directly contagious, although many authorities considered the malady which they studied to be so. Up to the present time the investigators have been unsuccessful in obtaining any serum or protective substance that will modify or ameliorate the course of the disease in experimental animals.

The Disappearing of the Old-time General Practitioner.

In the *Albany Medical Annals* for April is a memorial notice of Dr. Rial Strickland, a country doctor of the old school. Dr. Crothers, the writer of the notice, refers to its subject in the following apt phrases: "The bustling, resolute, independent doctor who was a surgeon and obstetrician, a neurologist, a chemist, a dentist, a veterinarian, and an undertaker on occasions, and who wrote wills, said prayers, and conducted funeral services, and did many other things unknown to the modern physician, belongs to the past century. Dr. Strickland was a marked type of this class. In the sixty-four years of his professional career he filled this rôle completely, and officiated in every possible way that a physician of long ago was called upon to do."

The old-fashioned country general practitioner has been driven out by modern methods of medicine. Of course in many ways he was behind the times, and somewhat of a relic of the past, but it cannot be truly said that the old country doctor is not missed, nor that his place is in many respects adequately filled. The opening up of the country by railroads has obviated the necessity of the country general practitioner being qualified to fill the numerous positions mentioned by Dr. Crothers. Yet, at the same time, it must be confessed that the modern substitute for this medical "handy man" is deficient in many of the qualities which distinguished his sturdy predecessor. In the days gone by, the country doctor was compelled to be self-reliant, the fact that he was so situated that he was unable to call in the assistance of a medical brother acted as the spur. If he was lacking in the self-reliant spirit, the practice of medicine in the country was clearly not his vocation. Under present conditions, however, the product of the medical schools is a better finished article than was the medical graduate under the old régime.

Nevertheless, one can but allow that in his day the old country doctor did yeoman service, and filled excellently well a position of great responsibility, accentuated, be it said, with not a few hardships. The passing of the old-fashioned country doctor—while after all but a necessary phase in the evolution of medical practice—cannot be regarded without certain feelings of regret. Such must be always the case when the old order changes for the new.

Observations on Tuberculosis in Marburg.

Dr. E. Schwartzkopf has recently contributed to the *Deutsche Archiv für klinische Medizin* an account of some observations made by him on a large number of cases of tuberculosis in the Medical University Polyclinic of Marburg.

It was noted that although hereditary influence or predisposition to the disease may be a factor in its causation, it could not explain why healthy persons should contract it after living in certain houses, nor why the malady should be so frequent among children in these houses.

From observations made in the hospital the writer states that "among the women in the hospital, 61 per cent. of those affected with tuberculosis had unquestionably been exposed to infection, while among those who did not have tuberculosis, only 24 per

cent. had been exposed to infection. . . . The danger of contracting tuberculosis increases with the number of patients in the neighborhood, and with the duration of the exposure. A case of infection in childhood which becomes real lung tuberculosis in the thirteenth year is rarely cured, and the chance of recovery is less if renewed infection takes place. After the age of fourteen years, a person becomes more susceptible to the disease, and the susceptibility becomes greater up to the age of forty. . . . As for inheritance of the disease, heredity has not the least influence in the origin of tuberculosis of the lungs. That depends upon infection."

According to the deductions drawn by Dr. Schwartzkopf from his observations, the danger from tuberculous parents does not seem to lie in an innate tendency to develop the disease, but in the great exposure to infection by living with such parents, and, in that case, there is more danger from the mother than from the father, because she is more closely associated with the family. The very frequent occurrence of tuberculosis among the children of the poorer classes was shown by post-mortem examination of the patients in the hospitals. Seventeen per cent. of all such examinations for children from one to five years of age showed tuberculous changes, and 33 per cent. of those from five to fourteen years of age.

News of the Week.

Dr. Einhorn's Works Translated into Japanese.—Doctors S. Nagayo of Tokio and Masuza Tanaka have translated Dr. Max Einhorn's book on "Diseases of the Stomach" into the Japanese language, a copy of which has just arrived. The same authors are also at present at work in translating Dr. Einhorn's book on "Diseases of the Intestines." This makes the fourth language in which this book has appeared.

The Drug Dramshop Law in St. Louis.—The St. Louis Court of Appeals handed down a decision recently which will prevent physicians, who are also pharmacists, from filling their own prescriptions the principal ingredient of which is whiskey. T. S. Manning of Audrain County, Missouri, was found guilty of violating the drug dramshop law and was fined $100. He appealed. His defence was two prescriptions written by himself for Henry Rivere. He said he had a right to prescribe whiskey as a physician and to fill the prescription as a pharmacist. The Court held that the requirement of a prescription is intended as a check on the pharmacist, and that if the same man is permitted to write and fill the prescription the check is virtually removed. It admits that some hardship may be worked on a physician who writes that kind of a prescription and is compelled to have it filled at a remote drug store, but it is held that his hardship cannot be permitted to frustate the intent of the law.

Bequest to Yale University Medical School.—By the will of the late Mrs. Henry Farnam of New Haven, Conn., the Yale Medical School receives a legacy of $54,500, as an addition to its general endowment fund.

Death of Frances Power Cobbe.—Miss F. P. Cobbe, one of the most prominent opponents of vivisection, and the founder of a monthly magazine in which the antivivisectionists aired their views, has just died. Miss Cobbe was the founder, and for eighteen years the honorary secretary of the Victoria Street Society for the Protection of Animals from vivisection. Since 1898 she had been president of the British Union for the abolition of vivisection.

Infant Mortality in Belgium.—The Central Section of the Belgian Chamber has unanimously adopted the suggestion of Dr. Delbastée forbidding the insurance of the lives of infants. Dr. Delbastée proposed that no child should be insured under the age of five years, but the Chamber lowered the limit to three years.

French Congress of Alienists and Neurologists.—The fourteenth annual meeting of the French Congress of Alienists and Neurologists will be held this year at Pau from August 1 to 7. Among the questions to be discussed are motor localization in the medulla, and the measures to be taken in regard to criminal lunatics.

The International Congress of Ophthalmology.—In response to numerous requests, the Executive Committee of the International Congress of Ophthalmology at Lucerne has resolved that the proceedings shall commence on September 13 and terminate on September 17. Only those papers will be discussed which have been handed to Professor Dr. Mellinger, Bâle, before May 1.

French Congress of Colonial Hygiene.—A Congress of Colonial Hygiene is to be held in Paris from May 29 to June 6, under the presidency of Professor A. Charrin. Professor Brault of the Medical School of Algiers is vice-president, and M. Alizaky, secretary of the Islam Committee. The French Government has given facilities to officers of the Army, Navy, and Colonial Service to attend the Congress.—*British Medical Journal.*

Fight for Pure Milk.—The Superintendent of Milk Insepction of Chicago is making preparations for a thorough inspection of all insanitary dairies, and hereafter the department will enforce a rigid compliance with the requirements of the ordinances governing the sale of milk in Chicago. In former years it has been the practice to issue licenses first and inspect afterward. But a new policy is to be begun. Every one of the thirty-five hundred dairies which furnish milk to Chicago will come under the searching eye of an inspector before the end of this month. Dealers who do not come up to the sanitary requirements of the city milk ordinances will be denied licenses. This rule is to embrace all places where milk is kept for sale, or for purposes of sale to agents, whether they are actually dairies or not. To make the preventive campaign more effective, the inspectors will insist on the sterilizing of all milk bottles. This, with rigid inspection of the sources of supply and the good work of the Pasteurizing plants, should insure a high grade of milk for consumers during the coming summer.

Music for the Insane.—The General Superintendent of the Hospital for the Insane at Dunning, Ill., believes that music will act beneficially on the minds of patients, and therefore music will be tried as a curative influence on the inmates. The musical instruments, which, with a supply of games, and a moving-picture machine, were purchased out a fund of $1,100 secured by donations, are later to be distributed to the various wards of the hospital and kept in use at all times. It is believed that these entertainments will take the patients' minds off their broodings and melancholy thoughts.

Committee to Bring About Unity of Action.—Closer affiliation between the Chicago Medical Society and the Dental, Homeopathic, and Eclectic professions is the object of a Committee on Public Relations, appointed by the Chicago Medical Society. The dental profession has already been approached on the question of closer relations among the various branches of the healing art, and the

proposition has met with favor. It is essential to secure unity of action on all questions of public policy.

Land Secured for Chicago Hospital.—Mr. John A. Markley has sold to Mr. McCormick one-fourth block of land at $40,000 for the construction of a hospital for the cure of infectious diseases, and a deal is under way for purchase of the remainder of the block. It is believed the hospital buildings will cost $500,000, while aside from this there will be a heavy endowment. It is said that Dr. Ludwig Hektoen will be the medical director of the institution, which will be in affiliation with the University of Chicago.

Gift to a Negro Hospital at Wilmington.—Mr. William H. Sprunt of Wilmington, N. C., has given $10,000 to build an annex to the James Walker Memorial Hospital, to be used exclusively for the negro race.

Cincinnati Filtration Plant.—A recent decision of Supreme Court of Ohio, upholding the validity of an additional bond issue for the new water works, will result in the pushing to completion of this large plant and will also give $1,000,000 for a filtration system.

Cincinnati Children's Home.—The endowment fund of the Children's Home was yesterday increased $200 from the estate of Miss Anna A. Warder, who recently died in North Bend, O.

New Cincinnati Hospital Internes.—In the competitive examination for internes at the Cincinnati Hospital, concluded recently, the Ohio Medical College won a signal victory over the Miami Medical College by gaining seven out of the eight internes to be selected. Those successful in gaining interneships were Jessie Wyler, Joseph L. Ransohoff, C.W. Smith, George S. Mytinger, Oscar Behrman, Oscar Berghausen, A. E. Osmond, and Edward B. Reemelin; alternates, O. D. Barker, A.F. Heavenrich, C. D. Heisel, and George H. Holt. The first-named four will enter upon their duties in May, while the others must wait until November. The alternates will fill vacancies.

Five Hundred and Fifty Dollars for Degree of M.D.—Charles Conrad, 56 West Fifty-sixth street, and J. White Bushnell, 5 West One hundred and fourth street, charged by the New York County Medical Society with practising medicine without a license, were arraigned in the West Side police court on April 15 and held for trial. "Dr." Conrad is said to have been a Norwegian sailor, who, as president of the Platen Institute, has done a thriving business. According to a woman agent of the Medical Society, he offered the degree of M.D. for $550.

The Health of the Czar.—There have been for the past few weeks many reports with regard to the state of the Czar's health. According to Mr. Henry Norman, the distinguished English writer and journalist, who is now in St. Petersburg and who had a long interview with the Czar on April 13, the accounts of the Russian ruler's physical and mental breakdown are false.

Fire at the Home for Incurables in New York.—On Saturday evening, April 16, a small fire was discovered in the Home for Incurables, at Third avenue and One hundred and eighty-first street. Mrs. Elliot, the head nurse, discovered the fire in a cloak room at the rear of the building. The medical superintendent, Dr. J. C. Jones, sent in a fire alarm, but the blaze was extinguished before the engines arrived.

Life's Elements in the Sea.—The New York *Sun*, April 17, publishes the following cable dispatch: "Ten years ago the injection of salt water as a restorative to patients dying from loss of blood aroused general interest. The discovery of t quality of salt water probably suggested to French savant, M. Quinton, a long and patient search concerning salt water, the conclusion of wh throws unexpected light on and adds support to Darwinian theory of evolution. M. Quinton ma tains that sea water is the natural source from wh as Professor Haeckel believes, elementary bodies which develop into all the species, including human. The environment wherein the anatom elements of living creatures exist is neither more less than a marine one. Our tissues and cells c tinue to exert their functions in a fluid, the comp tion of which bears the closest resemblance to t of sea water.

Death Benefit Plan for New York Elevated Rail Employees Rejected by Them.—A sick and de benefit and accident insurance plan framed by Interborough Rapid Transit Company for its ployees, has been rejected by the unions of employ on the Manhattan elevated roads. The objecti to the plan were chiefly because the men themsel paid all the money into a fund and might lose they had paid in if they were discharged or resig

Fire in a Hospital.—On April 17 a fire occu in St. Vincent's Hospital, Indianapolis. One wo was killed as the result of injuries received in l ing from a window, while several of the pati have suffered severely from shock.

Marriage Legislation.—A bill has been introd in the Ohio Legislature which provides that no son who is an imbecile, insane, a drunkard, or su ing from the effects of narcotic drugs, shall be eli to marry. Will the case rest in the hands of Probate Judge? Will it be his duty to say to a ing bridegroom, Are you a drunkard? Then question comes up, What is a drunkard? That will be hard to enforce, and perhaps, in part, wi held unconstitutional.

New College President.—At a meeting of Board of Trustees of the Central University, ville, Ky., held this week, Dr. F. W. Hinitt of field, Ia., was unanimously chosen President to ceed Dr. W. C. Roberts, whose death occurred eral months ago. It is thought that Dr. Hinitt accept.

A Cincinnati Sanatorium Fails.—With liabiliti indefinitely estimated at from $4,000 to $6,000, a assets at $2,000, the Brunton Sanatorium in Avo dale last week made an assignment to Attorney J seph Cox, Jr. The Brunton institution was estal lished about two years ago for the treatment of ne vous disorders.

The Indianapolis Medical Society.—A meeti of the society was held April 5 at the Central Ho pital for the Insane. The address of the evenin was delivered by Dr. F. W. Langdon of Cincinna on "Cardiovascular and Blood States and The Relation to Nervous and Mental Diseases."

The St. Clair County (Ill.) Medical Society elect the following officers: *President*, Dr. C. H. Starke *Secretary*, Dr. B. H. Partuondo; *Treasurer*, Dr. E. Lansing. It was voted to admit any reputab graduate of medicine, provided he be not a sectari practitioner.

Bacilli Exhibit.—Bacilli and germs will form th interesting exhibit of Dr. M. Miyajima, a note Japanese scientist, at the World's Fair. The spec mens which Dr. Miyajima will exhibit were co lected by Prof. Shibasaburo Kitasato, the wel known scientist of Japan. Dr. Miyajima is a instructor in the Imperial Hygienic Institute Japan and a personal friend of Kitasato.

ortable Hospital at Bellevue.—The authorities Bellevue, in order to relieve the overcrowding ch has prevailed for some time in the wards of evue Hospital, and to test the effect of the en-air" treatment of consumptive cases, have ted on the grounds of the institution a new ilion which will be devoted solely to the use tuberculous patients. The new pavilion is able, and is sixteen feet six inches by thirty- e feet in its dimensions, having accommoda- s for twelve patients. The building is con- ted of interchangeable sections, covered four from the foundation with clapboards, and ar- ed with adjustable awnings, and with sliding lows to admit the sunlight and air. The roof ade of canvas, having adjustable ventilating s, which are operated from the floor. Over roof is placed a canvas fly, leaving a space of t eighteen inches. By this arrangement a circulation of air is readily obtained.

ospital Bequest.—It is said that the late Solomon of New York left $5,000 to the Cincinnati Jew- Hospital. Mr. Loeb started in business in Cin- ati.

arborn County (Ind.) Medical Society.— meeting of the society March 29 a resolution passed endorsing the "Pure Drug and Food Bill" pending before Congress. Dr. Johnson of Moore's read a paper on "Fracture of the Forearm."

ituary Notes.—Dr. EDWARD A. HITE, a promi- Kokomo (Ind.) physician, died Friday, after an ation for appendicitis.

r HENRY THOMPSON, one of the most distin- ed British surgeons, died on April 18. He was y-three years of age. The deceased baronet born in Framlingham, Suffolk, of poor parents, was brought up and educated by the Framling- doctor. He operated on the late Emperor oleon III, and was surgeon extraordinary to the of the Belgians, consulting surgeon to Univer- College Hospital, London, and Emeritus Profes- f Clinical Surgery. Sir Henry Thompson was uated in medicine at University College, Lon- where he won honors. He was a man of great tility. In addition to being the author of erous papers on scientific and surgical subjects, rote several novels. He was also a painter of nean ability and a deep student of astronomy. te years he has been one of the foremost advo- of cremation.

r. JOHN A. PEARSALL, a prominent homeopathist New York State, died in Saratoga on April , aged fifty-three years. He was a member of the w York State Homeopathic Medical Society and the American Institute of Homeopathy.

Dr. SAMUEL SMILES, the author of "Self Help" d other well-known works, has just died in London the age of ninety-one years. Dr. Smiles was born Haddington, Scotland, on December 23, 1812. e received his degree of M.D. and also an honorary gree of LL.D. from Edinburgh University. He on, however, gave up the practice of medicine to come the editor of the *Leeds Times*. His most mous book was "Self Help," which was translated to several languages. His later years were spent uietly in Kensington, London.

Dr. JOHN W. ADAMS of St. Louis died at his home April 14. Dr. Adams was born in Franklin ounty, Mo., in 1865. He graduated from the eaumont Hospital Medical College (St. Louis) 1887, and at the time of his death he was Pro- sor of Physical Diagnosis in the St. Louis Col- e of Physicians and Surgeons. His wife and a ughter, eleven years of age, survive him.

THE HERTER LECTURES.*

BY PROF. PAUL EHRLICH,
FRANKFORT, GERMANY.
(From Our Special Correspondent.)

LECTURE III.

CYTOTOXINS AND CYTOTOXIC IMMUNITY.

PROFESSOR EHRLICH began his third lecture of this series with a brief description of the development of our knowledge concerning bacteriolysins and cytolysins. Although the ancients were aware of the fact that one attack of a contagious disease usually protected the same individual against subsequent infection, the first really scientific conception of the subject of immunity was published to the world by Jenner in his work on cowpox and smallpox. The second period was marked by Behring's discovery of antitoxin, and the great increase of the literature during recent years showed the importance which this domain of science had attained. Bacteriolysins, agglutinins, and cytolysins were next described, and among the authors mentioned in connection with the development of this part of the subject, he alluded to the importance of the recent work of Welsh on myelotoxin.

Professor Ehrlich then took up the mode of action of amboceptors and complements and stated that the interpretation of Pfeiffer, Metchnikoff, and Bordet's demonstration of the participation of two substances in producing bacteriolysis was made clear by means of absorption experiments and experiments at low temperature. In treating of the establishment of the amboceptor theory, he showed by the aid of explanatory diagrams that the amboceptor, which was the specific product of immunization, united by means of one haptophore group with the receptor of the susceptible cell, and by means of another group with the complement. The complement had one chemical group suitable for union with the amboceptor, and another, the zymotoxic complex, which caused the injury to the cells. In opposition to this, Bordet had devised the so-called "sensitization" theory, which the speaker, however, sought to refute.

For the theory of direct union between cell-receptor, amboceptor and complement, Ehrlich submitted the following evidence: (1) The fact that there were well-established chemical analogues, such as among the anilin dyes. (2) Complements might be side-tracked by an excess of free amboceptors, as was proved in the case of bacteriolysis by Neisser and Wechsberg and also firmly established for hæmolysins by the employment of anti-amboceptors by Morgenroth. (3) The existence of products which resulted from the breaking down of amboceptors—the co-called amboceptoroids. These were no longer anchored by the cell, but still were able to divert complements. The amboceptor then acted like a demordant. The complete hæmolysin thus formed an analogue of a toxin, in which one part, the amboceptor, corresponded to the haptophore group, and the second part, the complement, to the toxophore group.

Contrary to the conception of Bordet, the complement was not a simple unit, but was made up of a great many partial complements, which become attached simultaneously to the amboceptor. Accordingly, the amboceptor contained a whole series of complementophilic groups, and not a single one, as was first supposed. The various amboceptors which could belong to one animal species, differed specifically only in those haptophore groups which were concerned in the union with the cell, while they were practically

*Delivered at the Johns Hopkins University, Baltimore, Md., April 14, 1904.

identical, or at least similar, as far as their complex complementophilic component was concerned.

Proof of the multiplicity, as opposed to the unity, of complements might be shown by the method of partial absorption, by the selective instruction of single-partial complements, by the demonstration of anti-complements which inhibited only a certain part of the complement action, and finally, by the evidence brought forward by Metchnikoff, who showed that, by the disintegration of microcytes or macrocytes, at least two complements arose, which differed in their effects, one producing demolysis and the other bacteriolysis. In this connection it might be stated that in each individual instance of lytic action it was not necessarily the whole series of complements, but only a certain fraction, which he called the dominant complements, which was concerned.

The amboceptor theory was next discussed.

Amboceptors were cell products. In the protoplasm of cells, there were, in addition to the single receptors which gave rise to antitoxin, certain more complicated receptors, which became effective in the absorption of the more complex molecules. He distinguished two varieties of these receptors. In the first place, those which, in addition to their anchoring the haptophore groups, possessed a chemical complex which might induce coagulative processes. These were usually quite resistant to heat. As the result of immunization with cells or albuminous material, receptors of this order appeared in the serum as coagulins or agglutinins. Amboceptors might also arise from receptors of the third order. These were concerned with the fixation and assimilation of the largest food-molecules. For the catabolic changes in these molecules there were needed a whole sequence of processes, which could only be carried out by a multitude of fermentative agents such as the complements. These complements would be destroyed if the affinity of the complementophilic groups were such that the complements were continually being absorbed by the receptors. A wonderfully well-adjusted mechanism controled the complement absorption, for by the union of a haptophore group with a nutrient molecule, the avidity of the complementophilic group of the receptor was so augmented as to permit its combination with a complement. This was a sort of economy which enabled the labile ferment to reach the cell at exactly the favorable moment for its utilization.

Amboceptors could be produced by immunization which were specific antibodies for a great number of albuminous materials, and the speaker expressed the hope that the study of these amboceptors would give us a much clearer view than we could now obtain, into the process of assimilation. It must be assumed that those parts of the protoplasm which were the bearers of the receptors of the second and third orders must be completely immune to the destructive action of the zymotoxic groups of the complements. Although with the means at present at our disposal it was impossible to bring forward direct proof of the partial separation of these particles of protoplasm, yet we were forced to believe that such a separation did exist, from the fact that complements were able to destroy their own cells if they were artificially brought into relationship with certain other constituents of the cell. This was easily effected with the aid of cytotoxic amboceptors, which could be readily produced for nearly all kinds of cells. Thus the erythrocytes of a sheep, which were laden with hæmolytic amboceptors, would show no signs of injury so long as they are suspended in normal salt solution, but would be dissolved at once upon addition of the very same serum which had been removed from the sheep. Thus the most important agents of the body economy were turned into deadly weapons if brought into false relation to the protoplasm.

The last topic was the pleuristic conceptions of cells. The latter were systems of a very complex construction. Each possessed a great number of separate components which, from a purely theoretical point of view, were capable of producing an equally great number of specific reaction products. It was probable that each morphologically different cell constituent—that is, protoplasm, nucleus, etc.—was capable of producing a serum specifically antagonistic to this particular structure, which serum in turn might be made up of a whole series of partial components.

In dealing with protection against autointoxication, Ehrlich took occasion to comment on the term "horror autotoxicus," first presented by himself to express the suitable means which an animal had of regulating the production by the animal of certain substances. It was well known that by the injection of foreign cellular materials into animals, cytotoxic substances were produced, which were especially directed against the material employed for the immunization. In human pathology, however, we were not concerned with the resorption of foreign bodies, but of those which originated in the organism itself, as shown where hemorrhage had taken place into cavities, where the absorption of lymphatic tumors had taken place, and in other instances.

An immune serum in the former restricted sense of absolute specificity did not, however, exist, and we could speak only of the specificity of one amboceptor type for one definite causative substance. Since the immune sera contained a great number of different fractional components, which, in turn, could occupy a correspondingly great number of receptors—furthermore, since not the whole number of receptors of any one cell were peculiar to this cell, but a variable number of them were also common to other nearly related cells—we must conceive that serum produced by immunization with a certain type of protoplasm, while it exercised its chief action against this protoplasm, also exhibited its action upon a whole series of other substrata of protoplasm. The more closely related the receptor apparatus was of two immunity producing agents, the more completely did the sera produced by them correspond in their action.

In closing, Professor Ehrlich referred to certain topics from a very extensive domain pertaining to this subject of pleuralistic conceptions:

1. The controversy over alexins. These, formerly supposed to be simple units, corresponded to a very great number of agglutinins and amboceptors. These normal substances, destructive to the cell, might arise homologously (*e.g.* the cololysins), or heterologously (cholera amboceptors of the goat, trypanosomacides of human serum). It should be the aim to obtain for therapeutic purposes in this serum not only the complements, but especially the powerful curative amboceptors of normal organs.

2. Alterations in the receptor apparatus of the blood corpuscles and their relations to the isolysins, as shown by Koch, in the isolysins of coast fever.

3. The determination of philogenetic relationship, as exemplified in Uhlenhuth and Wassermann's blood test for forensic purposes.

4. The relationship between the virulence of bacteria, the receptor apparatus and the development of immunity, as proved by Hamberger, Wasserman, Walker, Pfeiffer, and particularly by Welsh.

5. Practical results from the production of bactericidal sera. These must contain many amboceptor groups for various species.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

MARMOREK'S SERUM TREATMENT — PROSTATECTOMY — MUNICIPAL MILK SUPPLY—ARMY COUNCIL—ABUSE OF IRISH POOR LAW—INFANT FOOD AND PATENT MEDICINES—SIR W. CHURCH—HOSPITAL APPEALS AND FINANCES.

LONDON, April 2, 1904.

PROF. A. MARMOREK has been over here, and last week read a paper at St. George's Hospital on treatment with his antituberculous serum.

He began with stating that the human organism is refractory to the tubercle bacillus, and of those who show symptoms of infection 20 per cent. recover through their own natural immunity. From twenty to twenty-two recoveries also occur under the different methods of treatment. Hence the same number of people get well whether treated or not, still treatment is of use to those who vacillate between natural immunity and lack of it. Dr. Marmorek believes that tuberculin does not play the rôle which has been attributed to it, but that it is really only a reactive which causes the bacilli to secrete another toxin, hitherto unknown, and this new toxin is the weapon with which the bacilli attack the organism.

Treatment with tuberculin is active immunization by means of the toxin secreted in the dieased organism, and may sometimes produce favorable results, but they are only exceptions, because we cannot control the amount of toxin produced in this indirect way.

The dangers of this treatment are well known, but disappear when this active immunization is replaced by the surer passive immunization induced by his antituberculic serum. Tuberculosis, with its chronic course and variations, is not to be compared with acute diseases like diphtheria or plague. The death rate would not show the value of the serum for years. Hitherto slight cases have been selected for treatment by various methods, but Dr. Marmorek says that we cannot in any case tell whether such would be amongst those capable of self-recovery or not. He therefore began with severe cases. He wished to descend the latter from the top to the bottom, and not the reverse plan followed by his predecessors. He anticipated extraordinarily advanced cases could not be affected, but was determined to find out at what advanced stage the serum would begin to take effect. So at first he treated all cases, even the very worst, with the serum. Most patients show no serious reaction, but a few cannot support the treatment. The earlier the infection the greater the probability of benefit. In chronic cases with acute extensions the most recent lesions are first healed while the older parts with loss of tissue, etc., take a longer time to rebuild. The serum is directed against the primary effects, and if only primary lesions have occurred a complete restoration is obtained. Even in the most acute form of tuberculosis, viz., meningitis, Dr. Marmorek does not despair of some day attaining success, and in the hope of doing so, has devised a method of arriving at earlier diagnosis by testing the spinal fluid. To the question whether his serum can cure pulmonary consumption by its specific action, Dr. Marmorek answers, without reserve, Yes. Among his cases I cite one complicated with laryngeal disease which had passed six months in a sanatorium without benefit. After seventy-seven injections the patient felt well, and the bacilli had disappeared from the sputum. This patient interrupted the treatment, and went into the country with the result of a relapse, but on renewing the injections, after some months, completely recovered.

In reference to clinical symptoms, serum reduces hectic, but if streptococci are present, Professor Marmorek advises alternating with the appropriate serum. If no streptococci are present his serum suffices. Dyspnœa also yields to the treatment almost without exception. Bacilli decrease as the sputum becomes less. As in other cases, they may be found for a long time after symptoms have disappeared, and it is an open question whether they may not exist merely in saprophytic life. One would hardly expect the serum to control hæmoptysis, and yet Dr. Marmorek has had cases which had previously suffered from several attacks which did not recur under serum. He mentioned the fact, but did not pretend to decide whether it was accidental or not. Then he showed photos of surgical tuberculosis relieved, and finally assured us that he had never seen any serious consequences due to the treatment by his serum.

Surgeons do not seem able to agree as to the completeness of the operation which they have called prostatectomy. The question came up again at the Medico-Chirurgical Society in a paper by Mr. Thomson Walker, which he devoted to the surgical anatomy of the normal and enlarged prostate, and to the operation in question. He described four specimens of the parts left behind after the suprapubic operation, and then considered the seventy-three specimens of prostate removed by Mr. P. J. Freyer, dividing them into two groups—those entirely extravesical, and those with an intravesical portion. In some of the specimens nodules of prostatic tissue were left behind, but held this could not vitiate the completeness of the prostatectomy. The real question he held was whether the line of cleavage passed between the prostatic capsule and the sheath, or along some plane within the capsule, or even within the gland. His investigation supported the contention that the gland was removed within its capsule, and the sheath left behind. Recent statements to the contrary were based on insufficient evidence, and could not be accepted as applying to the operation under consideration. Shreds of gland tissue left behind were mere accidents, and not proofs of incomplete operation.

Mr. Reginald Harrison said that from study of his own specimens he concluded they embraced both results; in some, the gland was completely shelled out, in others a distinct portion of prostatic tissue was left behind.

Mr. Cuthbert Wallace remarked that it was admitted the normal gland could not be enucleated, and asked how it was that specimens weighing little more than normal were removed as easily as large ones. In one of Mr. Walker's specimens a small adenoma in the capsule was left. Clearly this represented part of the prostate, for it could only have arisen from preëxisting gland tissue, so that histologically the operation was not complete. Mr. Wallace dealt also with the possibility of leaving the urethra intact, expressing the opinion that with small tumors this might be, but not with large ones.

Mr. Swinford Edwards said that in some operations there was extracapsular, in others intracapsular enucleation. Great relief was the usual result for the patients.

Mr. Pearce Gould said when an organ came within the scope of the operating surgeon many fine anatomical points got cleared up. He quite agreed that the question of extra- or intracapsular enucleation depended on the plane of tissue opened, and mentioned a case in which he had removed six adenomatous masses from the prostate and yet it was not a complete prostatectomy. The value of the operation could not be doubted.

Mr. Pardoe suggested that prostatic tissue might rupture the capsule and pass within the plane of that tissue.

Mr. P. J. Freyer considered that the whole capsule was removed and a complete prostatectomy performed. To sum up the foregoing discussion: Cannot we reconcile the two views by saying surgically it is prostatectonus, and histologically it is not complete when gland tissue is left behind? The question is of mere academical interest. The great thing is that patients are generally greatly relieved.

The municipal milk supply is making fair progress. Battersea has followed Liverpool with considerable energy and success. Respecting the latter, Dr. Hope has recently communicated important particulars as to the care with which the milk supply of Liverpool was superintended. He described the plan of distributing sterilized milk, and as it is being called, humanized milk, to the poor of Liverpool. This milk is supplied in baskets of nine bottles, containing a sufficient supply for twenty-four hours, no bottle being used twice. The value of substituting pure, clean, suitable food for the contents of an evil-smelling feeding-bottle and the promiscuous bits often given to babies cannot be doubted, and the statistics already accumulated prove the point. Out of more than 6,000 infants fed on this milk it was possible to keep records of 4,453, about half of whom were ill when the food was first given them. The rate of mortality was 78 per 1,000. The causes of death showed no peculiarity, bronchitis, pneumonia, whooping-cough, convulsions, and so on, prevailing in the certificates. This rate compared very favorably with the ordinary infantile mortality of the city, especially considering the great proportion of sickness amongst them when the feeding was begun.

Of all plans of artificial feeding this would seem the best; but, of course, no substitute for mothers' milk can be perfect, and Dr. Hope and his committee fully recognized this. They make no claim that their plan is ideal—only that it has saved many lives and restored many sick infants to health—diminishing thus the mortality and improving the stamina of the city's infant population. The corporation can never relieve the mothers from their duty to their children, and every card issued contains instructions to the effect that the milk is intended for infants whose mothers are unable to suckle them.

It must be admitted that, however good the milk and however carefully prepared, it must be inferior to the food provided by nature. As Dr. Welch remarked in his Huxley lecture, human breast milk is immune, or par-

tially immune, from many diseases, and probably confers some immunity on the infant. Again it passes directly from the breast to the infant without exposure to the air, and so undergoes no abstractions, adulterations, preservatives, or other admixture or uncleanness. It is bacteriologically pure and cannot be equalled by any substitute. It is therefore most satisfactory to learn that Liverpool is educating its mothers up to this point.

At an inquest on Wednesday the coroner contrasted London's lack of ambulances with the system in New York, which he pronounced excellent. Our County Council has the matter under consideration, so may possibly take a leaf out of your book.

The secretary of the Mount Vernon Hospital was summoned for Rates on Wednesday and pleaded that the hospital was £15,000 in debt, and at the last Finance Committee meeting had no funds after paying servants' wages due. I am afraid it is another case of overindulgence in bricks and mortar.

The head of the medical service is to have no seat in the new Army Council, as he can be asked to attend when his special knowledge or advice is desired. We may be sure our "Military Advisers" will go on in the old way and never send for him unless they want a scapegoat for their blunders. Sir Michael Foster, as soon as Parliament reassembles, will ask if the House will not have an opportunity of discussing the matter before action is taken on the report so far as it concerns the health of the army.

For shameless abuse of medical charity perhaps Ireland holds the record. No one appears to find any difficulty in obtaining a free ticket for the Poor Law Doctor's attendance, and what is worse, no one seems ashamed to beg one. Tradesmen, contractors, shopkeepers, mill-owners, etc., commonly avail themselves of the poor-law service and yet would resent being described as paupers, or imposters, or as beggars. On Saturday the Coleraine Guardians achieved great distinction by the unheard of proceeding of cancelling two free tickets. It was stated at the meeting that the doctor had been called upon for free attendance by two families who had a balance at the bank of £500.

Sir W. S. Church has been reëlected president of the Royal College of Physicians.

The Lunacy Commissioners have directed the Committee of the Portsmouth Asylum to accept the resignation of Dr. Henderson and Miss Watson in consequence of the recent error when four female patients died from chloral. A solution was used the strength of which seems to have been misstated. The committee has adjourned the consideration of the report, not thinking the accident requires resignation.

The North West London Hospital is making a strong appeal for funds, and states in *The Times* that Mr. George Herring, the treasurer, has promised to add one-third to the amount received. This is the gentleman who added to the Sunday fund collection more than £10,000 on the last two occasions.

THE USE OF THE LIBRARY OF THE ACADEMY BY NON-MEMBERS.

To the Editor of the Medical Record:

Sir: In your issue of April 2, Dr. A. Jacobi, in defending the new rule of the Library of the Academy of Medicine (whereby the medical public has now but little access to this valuable "public" library), endeavors to make it appear that I am also the author of an anonymous communication to a New York medical journal. This I emphatically deny. My only comment, or criticism, concerning the Academy has been in regard to its stringent library laws and then only in the Medical Record of March 26, and under my own signature. Dr. Jacobi says that for many years the Academy has been very generous to the medical and lay public. But he omits to say that this generosity (?) was compulsory, owing to the fact that the Academy poses as a public educational institution with a *free* public library, and on this account has taxes remitted on the Academy building. The following letter, which I received from the Commissioner of Taxes, shows that the reason the academy is exempt from taxes is because upon investigation of the tax department it found the Academy maintained a public library, open daily from 9 A.M. to 5 P.M. The letter from the tax commissioner of April 7 reads in part as follows: "I beg to advise you that the question of exemption of this property (17 W. 43d street.) has been before the commissioners a number of times. At its old home, 12 West Thirty-first street, its property, which was used in a similar way to the present property, was exempted from taxes in 1885–1886 by a supreme court decision because it was a public library.

"In 1891 the question of exemption of this property came up, and after considerable hesitancy, it was decided favorably by the commissioners.

"In 1896 the question was again before the department of taxes and assessment, and on the affidavit of the treasurer of the board of trustees, as to ownership, occupancy and the use of these premises for the purposes of the society, and on the report of the deputy, that he found that the entire second floor has a library *free* to the public from 9 A.M. to 5 P.M., the commissioners again exempted from taxation. In 1901 . . . at this time the commissioners made an exhaustive examination, and decided that because this property was owned by a corporation organized exclusively for the mental improvement of men and women for educational, scientific, and library purposes . . . it was still entitled to exemption."

Thus from the foregoing letter, it is apparent, that if the Academy of Medicine still purposes to be exempt from taxes it will be necessary to permit physicians in general although not members of the Academy, to have the use of their library during such hours as other public libraries are open.

Samuel G. Tracy, M.D.

April 11, 1904.

ANÆSTHETIZED DURING SLEEP.

To the Editor of the Medical Record:

Sir: During the past winter, I have successfully anæsthetized with chloroform, while sleeping, ten patients for operation at the Hospital for Ruptured and Crippled.

As instructor in anæsthetics in this institution, I have had ample opportunity for testing this much-mooted question, and find there is little difficulty in producing rapid and profound anæsthesia without the slightest struggle or apparent consciousness. My cases have all been children, ranging in age from four to nine, but there is no reason to believe that a child waiting its turn for an operation should sleep any more profoundly than an adult. I use the Esmarch inhaler and dropper, and am careful not to touch the patient at first, but hold the mask close to the face. After the primary stage, I then switch to ether, and invariably they take the anæsthetic well and less of it, and have less nausea following. I doubt if one could be anæsthetized with ether while asleep without their knowledge, unless they had been previously drugged with alcohol, morphine, or some other narcotic.

My usual method for anæsthesia is with the Bennet cone, commencing with nitrous oxide gas, followed by ether.

These cases were merely for experiment.

Preston Satterwhite, M.D.

New York, April 11, 1904.

A Case of Full Term Extrauterine Pregnancy.—Czyzewicz reports this unusual case. The patient was a iv gravida in her eighth month. It was found that while the fœtus was distinctly palpable and was of the proper size for the period of gestation, the uterus was very moderately enlarged and was empty. A month later labor pains began in the empty uterus and the fœtus was removed by laparotomy. The hemorrhage following the removal of the placenta was so severe as to necessitate the ligation of both broad ligaments, and the patient died the next day of shock. The child was small, but well-developed, and lived.—*Zentralblatt für Gynäkloogie*, No. 4, 1904.

Good Feeding in Infancy.—Dr. A. Belcham Keyes, in a lecture before the School of Domestic Arts and Science of Chicago, recently reviewed what good feeding in infancy prevents: (1) It lessens the number of cases and mortality from acute intestinal and infectious diseases. (2) It avoids the distressing condition known as English disease or rickets, from which a large number of children die annually, and, if they survive the disease, are often deformed for life. (3) A large number of the cases of tuberculosis, especially of the bones, in young children are predisposed to the disease by the catarrhal condition of the intestines, in which conditions they take into the circulation the bacillus of tuberculosis, which the imperfect inner lining of the blood-vessels of the long bone makes a good resting-place, with its resultant chronic invalidism, and later frequent implication of the lung and death. (4) Proper infant feeding, even if these first three escaped, is a necessity for the good health and perhaps even the formation of the character of the child that later will become the man, and this is the preservation of the health and character of the American-born man

Progress of Medical Science.

The Boston Medical and Surgical Journal, April 7, 1904.

Infectious Arthritis.—Joel E. Goldthwait states that infectious arthritis may result from practically any of the infectious or pus-producing organisms, and the type of the lesion or its character will depend upon the special organism involved. The disease may be mild and of short duration, or it may be very severe, with much suffering, and, at times, fatal termination. One or many joints may be involved. The symptoms depend upon the severity of the infection. The joint lesion in infectious arthritis is generally of the nature of a toxæmia. The organisms are not found in the joint, but the symptoms all suggest the result of an infection. The origin of the infection is important. At times it can be definitely determined; at other times this is impossible. The result of the infection depends upon the organism from which the infectious element is absorbed. In the differential diagnosis of infectious arthritis from the other types of rheumatoid disease, in case the history, the general appearance of the patient, and the local lesion is not distinct, the *x*-ray is of the utmost importance. In infectious arthritis the bones are of normal density; the cartilage is present and of normal thickness, and although the joint may be ankylosed, this is due to the adhesions which have resulted as a part of the inflammation. If the arthritis goes on to more distinctive changes in the repair there may be new bone formed about the joint and true ankylosis result, but the appearances are entirely different from the atrophic or rheumatoid arthritis. The blood in infectious arthritis in the beginning and during the active stage shows a marked increase of the leucocytes, with usually a high percentage of hæmoglobin. As the disease progresses, the increase of leucocytes gradually disappears and the percentage of hæmoglobin becomes less. The lymphatic glands are almost always somewhat enlarged in the beginning, but when the toxæmia has been overcome it gradually and entirely subsides. If the infectious process is quite profound, the urine shows the characteristics of a septicæmia, and otherwise it is not peculiar. It is essential that the eliminative functions be kept as near the normal standard as possible. For the local treatment there is little to be done other than to protect the affected joint, and by means of hot applications and liniments to relieve the discomfort. When operation becomes necessary, the joint should be as thoroughly explored as possible, and the opening be made on both sides. The writer appends notes of various cases.

The Boston Medical and Surgical Journal, April 14, 1904.

Bilateral Facial Atrophy, with Report of a Case and Its Treatment by Subcutaneous Infection of Paraffine.—Benjamin T. Burley presents the history of a very interesting case. The atrophy came on when the patient was eleven years of age. It resisted all treatment. At the age of twenty-three she was seen by the writer. She was evidently not of nervous temperament. The subcutaneous tissues from the orbits to the chin and back to the ears were apparently entirely wanting. There was a marked depression in each cheek. After observing the patient for two months, the writer began the paraffine injections. At the first sitting 1½ c.c. of paraffine of melting point, 109.5°, was injected below each molar process. Aside from a slight prickling sensation, coming on occasionally for the next day or two, which was easily relieved by alcohol bathed over the areas, there was no discomfort. In all, nine treatments were given, the last three largely to make the surface uniform. The result was most satisfactory. The paraffine is expected to give way gradually to new tissue formation.

Journal of the American Medical Association, April 16, 1904.

Insufficientia Pylori.—This disease is discussed by M. I. Knapp, who has the following views as to dietetic treatment: The object is not to introduce any acid food nor food which develops gases. Sweets very quickly form acids in the digestive canal, consequently also these will be omitted from the dietary. Coffee, tea, spirits, fermented liquors, CO_2 containing waters, too much milk, cabbages, peas, beans, radishes, turnips, spices, salads, whole-grain bread and other cereals with their husks (the easily fermenting cellulose) on, fruits, especially grapes, peaches, plums, and prunes should be forbidden. Excluding these, the patient has a free choice of food but not of drink. Clean, filtered water and milk are about all the patient can have.

Surgical Treatment of Nephritis.—A. H. Ferguson gives his experience with this measure, dwelling especially on the history of a case occurring in a young girl suffering from nephritis and floating kidney. The results were excellent, and six years later she was well. Points of interest in the case were: (1) That her right floating kidney was fastened a year previously by stitching it in place by a good gynecologist, without splitting or peeling off the capsule, but thereby she was not relieved. (2) Decapsulation relieved this same kidney of pain and tenderness. (3) The double decapsulation so far has cured her interstitial nephritis. He also reports two other cases, one of renal decapsulation and puncture for acute diffuse nephritis with a fatal result. In this case chronic interstitial disease was present with every evidence of granular kidney without any previous symptoms or signs. If a microscopic examination of a portion of the kidney had not been made, the case would have gone down in history as one of acute nephritis. (2) The severity of the acute diffuse nephritis, without other apparent cause than exposure to cold was, in the author's view, remarkable. It was so severe that it might be called "hemorrhagic nephritis," which, however, is more characteristic of intense septic and infectious cases. (3) Operation was of no avail, because it was to late in being performed. In a second case double decapsulation was done for interstitial disease and this patient recovered. The author considers that floating kidney may be regarded as one of the indications for decapsulation.

The Surgical Relation of the Vermiform Appendix to Perforation in Typhoid Fever.—L. J. Hammond states that the appendix is the seat of perforation, according to Cushing, in 9.6 per cent. of typhoid. Other observers have reported varying percentages down to five. He believes that a large number of cases occurring in the ileum and ascending colon that can be directly traced to preëxisting disease of the appendix, and quotes two cases bearing on this view. When the appendix has once been inflamed, a disease like typhoid fever is sure to light up a recurrence, and, as at best its powers of resistance are poor, it could hardly be expected to escape rupture within the organ itself, or what would seem more often to take place, rupture of a Peyer's patch, which, if not actually caused by impairment of the function due to preëxisting disease in the appendix, may be regarded as at least favoring it. It is within the power of the surgeon to reduce the mortality in perforative peritonitis in typhoid fever from 80 per cent. to 73, first by eliminating the appendix as a factor *per se;* second, by freeing the agglutinated intestines from adhesions caused by previous attacks of appendicitis, which afford possibility of still further serving as prophylaxis against occurrence of perforation in the ileum. Most observers agree that acute appendicitis, occurring during the course of typhoid fever, is merely a coincidence, and is probably in no instance the result of the bacillus of Eberth, nor to the general infective process resulting from the fever.

Medical News, April 16, 1904.

Poisoning by the White of an Egg.—J. R. Clemens describes the case of a boy of fourteen months who has had four attacks of intoxication following the ingestion of the white of egg. There were no incubation periods. In the first attack, the child was suddenly seized with an attack of acute urticaria and alarming collapse, the face and ears being greatly swollen and the radial pulse withdrawn from the wrist. Hypodermics of strychnine brought the child from its apparently moribund state. Two weeks later a similar attack occurred. Both times the child had been given the white of egg with his milk, which was an innovation. The third attack occurred after the patient had eaten custard. A little later, after eating ginger bread for which two eggs had been used, the child's feet became extremely swollen and purpuric. Treatment consisted in cleaning out the gastro-intestinal tract with oil, followed by full doses of calomel and later by salol and magnesium sulphate.

Hepatectomy for Tuberculoma of the Liver.—Joseph Ransohoff reports a case that came under his care. The patient was a man, aged thirty-six years. Ten years before the present illness the left testicle had been removed for tuberculosis. The patient's health had been excellent since then until four months before he entered the hospital in October, 1903. During this time he felt a sense of weight and then of pain in the pit of the stomach. There had been no nausea nor vomiting. A tumor for the past two months had been noticed under the tip of the sternum. On examination the tumor seemed very mobile. The dulness over the tumor was directly continuous with that over the liver. The stomach was normal in motility and secretion. Diagnosis was made of tumor of the liver, probably primary in character and of cancerous nature. Operation showed that what was felt as the tumor mass was found to be the left lobe of the liver, hardened and nodular on its lower surface, but quite movable. A second tumor was not felt. The writer determined to remove the tumor by resection. To this end an oblique incision three inches in length was made to the right. The left lobe of the liver was brought into

the wound, and two large, blunt-pointed bullet probes were passed at right angles through the thickness of the liver, an inch or more beneath the tumor mass, and an elastic tube thrown round the liver to form a pedicle. The operation was to be completed at another sitting. The lower part of the wound was closed in the usual way, the upper part slightly packed with gauze. Hemorrhage took place during the morning, and it was found that the elastic tourniquet had forced the skewers through the liver tissue, producing slight lacerations from which the hemorrhage came. The band was removed, and by means of one of the skewers a very heavy ligature was made to take its place. There was no further bleeding. With the thermocautery the left lobe was cut away with no further loss of blood. Death occurred on the sixth day after operation, probably from necrosis of the gastric mucosa from retrograde thrombosis of the omental veins. Careful examination after death makes it almost certain that the case was one of large tuberculoma. A nodule similar to the one in the left lobe, and half the size, was found in the right lobe on the upper surface of the liver close to the peritoneal reflection. The writer believes this to be the first case in which a resection of the liver has been made for a tuberculous tumor.

Ulcer and Cancer of the Stomach, from a Surgical Standpoint.—William J. Mayo declares that the most important subject before the medical profession to-day is that of diseases of the stomach. He first considers gastric ulcer. The etiology of this disease is obscure. The three known factors of great importance are anæmia, hyperchlorhydria, and mechanical injury. Chronic ulcer of the duodenum should be classed with gastric ulcer. It is essentially a disease of adult males. The symptoms of chronic ulcer are variable, but the chief one is pain. Indications for the surgical treatment of gastric ulcer can be divided into two distinct classes: First, the ulcer itself; second, the complicating adhesions, deformities, obstructions, and so forth. There are clinically three varieties of gastric ulcer: the mucous erosion, limited to the superficial epithelium; the round and fissure ulcer, limited to the mucous coat, except in perforative cases; the large irregular ulcer invading all the coats of the stomach. The keynote to the surgery of gastric ulcer is drainage, and the best place for this is to the left of the muscular pyloric part. The four methods of inducing gastric drainage are: The Heinike-Mikulicz pyloroplasty, which does not give satisfactory ultimate results in more than 70 per cent. of the cases; Finney's gastroduodenostomy, a most excellent operation, most useful in narrow strictures and least successful in open ulcer; Rodman's operation; gastrojejunostomy. Gastric carcinoma is the most frequent form of cancer in the human body. In the writer's experience of forty-three radical operations for malignant disease of the stomach, all but two who survived the operation lived beyond the year; one lived three years and seven months, and several are alive and well more than two years after. The mortality depends largely upon the case. In an early operation upon a patient not materially reduced, the mortality will not exceed 10 per cent. Much of the danger depends upon the adhesions to neighboring viscera. The writer believes that the diagnosis cannot be made in time by medical means. It can be surmised, but not often diagnosticated with certainty. Exploratory incision is practically harmless; a tumor of itself does not mark inoperability. In the writer's experience, the larger number of cases with symptoms of gastric cancer in which no trace of a tumor was present at the pylorus and without symptoms of obstruction have proved to be hopeless cases of cancer of the body which gave no early symptoms. Laboratory diagnosis of cancer of the stomach has little importance during the operable period because the disease is of too slight extent to interfere with the secretions. When it does so it usually means a hopeless involvement. Cancer of the stomach can be cured without excessive mortality only when exploratory operation is undertaken.

New York Medical Journal, April 16, 1904.

Ureteral Catheterism as a Routine Method of Diagnosis in Renal Disease.—The advantages of this method are thus summarized by J. Van der Poel, who prefers the cystoscope to other instruments: (1) The cystoscope is more easy of introduction than are the separators or segregators, is less painful during the bladder manipulations, and much less so during the collection of the urines. Hence, as a rule: (2) With ureteral catheterism we can collect the urines during as long a time as may be thought necessary, the patient not requiring any supervision. (3) A cystoscopic examination of the bladder can be made at the same time, which, in some cases, is useful, in others, indispensable. (4) We are much more certain of the exact results, especially when the two urines are of a similar character, whether clear, bloody, or purulent. and (5) It is the only method by which we are fairly certain that there is no bladder contamination.

Penetrating and Perforation Gunshot and Stab Wounds of the Abdomen with Report of Cases.—The report is made by J. G. Brown. Analysis of the cases shows that nine were cases of perforating wounds of intestines, with six recoveries and three deaths. Of the deaths, one was due to shock, the injuries being so extensive that patient never reacted. The second patient entered hospital with general peritonitis, and while a perforation was overlooked it is probable that the result would have been the same if this injury had been repaired. The third patient should have been saved, but a small wound in the bowel was overlooked. Of the wounds of the liver—five cases in all—four patients recovered and one died. This patient died three hours after operation from shock, the result of hemorrhage. In a wound of the pancreas case the patient recovered. To these cases he adds eight cases in which laparatomy was performed and no injury to viscera found. This makes a total of twenty-three cases, with nineteen recoveries and four deaths.

Ergot in Typhoid Fever.—A. T. Livingston advocates the use of this remedy which he uses hypodermatically. He claims that from it we can obtain prevention or relief of general nervousness; insomnia, or delirium, all of which depend chiefly upon congestion of nerve centers; prevention or relief of headache and of abdominal pains and discomfort, and of any pain that depends upon congested blood-vessels; relief or modification of tympanites by stimulation of the muscular coat of the bowel and by modifying the congestion and inflammation that disturb the functions of the bowels; hence, also, better general action of the bowels; modification of the local inflammation, thus lessening the likelihood of hemorrhage or extreme ulceration or perforation; prevention or relief of excessive sweating; better eliminative action of glands generally, thus aiding the natural activities in removing both septic and waste elements; reduction of frequency of pulse and strengthening of the heart's action; lessening the likelihood of complications by securing improved general vascular tone; and, finally, preventing exhaustion of the heart by removing the chief obstacles to its free action—areas of vascular congestion; for if we relieve the internal congestions, the heart is better supplied with blood to pump through the peripheral vessels.

American Medicine, April 16, 1904.

An Efficient Army Medical Service.—James S. Kennedy calls attention to the new "bill to increase the efficiency of the Medical Department of the U. S. Army." This bill will do away with the impossible contract system entirely, and in its place there will be organized a commissioned force of experienced medical officers (reserve) with actual rank and its privileges, and in number no more than are now serving under the present régime, for the surgeon-general will not recommend any officer for appointment who has not passed a satisfactory examination, and whose services have not been of the highest character as to efficiency and professional ability.

A Case of Pemphigus Vulgaris, with Some Observations on Its Bacteriology.—A. C. Eustis, after giving the history of a case, concludes that: (1) In cases of pemphigus a diplococcus can be isolated from the contents of the bullæ. (2) This diplococcus when injected intravenously into the rabbit will cause death. (3) A diplococcus removed from the blood of the rabbit and identical with that obtained from a case of pemphigus vulgaris, when injected into the pig, produces a pustular eruption in the latter animal, attended with mild constitutional disturbances. (4) Arsenic is the main remedy to be relied upon in the treatment of pemphigus vulgaris.

The Lancet, April 9, 1904.

A Non-toxic Preparation of Iodine.—H. V. Wyatt Wingrave has sought to find a preparation of iodine which could be given internally in large doses for considerable periods without causing symptoms of iodism, without sacrificing its specific effects on lymphatic enlargements. He has finally settled on the following formula: Iodine 2½ grams; tannic acid, 4 grams; alcohol (90 per cent.), 38 c.c., and syrup q. s. ad., 75 c.c. The iodine is dissolved in the alcohol, the tannic acid and 30 c.c of the syrup are added, the solution heated to just below the boiling point until it affords no evidence of free iodine with the starch test (about twenty minutes), then cooled and the remainder of the syrup added with a flavoring agent. Each dram contains 2 grs. of iodine. It should be given in dosage according to age, in water or wine, before meals. It is particularly well borne by children with lymphoid overgrowth.

The Use of Dr. Marmorek's Antituberculous Serum.—Arthur Latham gives his personal experience with this mode of serotherapy in a series of cases, being led to its

employment from his being impressed with Marmorek's argument against tuberculin being the real toxin in tuberculosis and in favor of his own new toxin by means of which the serum is prepared. Latham briefly reviews the technical directions for the injections and dwells upon their effects as referable both to the mere serum and to its antitoxin element. He states that in the majority of instances his patients have expressed the definite opinion that they feel more comfortable for the injections. In three cases out of the six treated of surgical tuberculosis, the pain and tenderness disappeared completely after a few injections had been given. In the majority of cases of pulmonary tuberculosis the first few injections led to an increase in the weight of the expectoration and to an increase in the number of moist sounds. In a certain number this increase was followed by a diminution in the weight of the sputum which was progressive, together with a diminution in the number of adventitious sounds. These results were sometimes more marked than they are when the serum is being used. The author cautions against too sanguine interpretation of these and like results, and declares that more experience must be accumulated and the cases watched for a longer period before we can draw any positively valid conclusions as to the efficacy of this serum.

The Cardiac Dulness in Cases of Cancer.—W. Gordon states that some years ago, in the examination of patients with gastric cancer, he noted that although no evidence existed of ordinary emphysema, the area of cardiac dulness, mapped out in the recumbent position, was either much reduced or actually obliterated. In some of them in whom the dulness was obliterated the resonant note over the heart was, it is true, slightly higher pitched than over the lung, but it was definitely resonant, not dull. The reduction or obliteration of the cardiac dulness was sometimes associated with a rather surprisingly small and soft pulse. His convictions as to the diagnostic value of these facts are expressed in the following statements: (1) Great reduction or obliteration of the normal cardiac dulness is common in cases of cancer, particularly in cancers of the alimentary canal and in their late stages. (2) This loss of cardiac dulness does not seem to be found in the earliest stages of a cancerous case, but may precede cachexia, marked wasting, and loss of skin elasticity. (3) It is rarely observed in non-cancerous cases. (4) It is rarely absent in the later stages of cases of cancer of the alimentary canal. (5) It does not seem to occur in cases of sarcoma. (6) In doubtful cases its presence is highly suggestive of cancer; its absence is slightly suggestive of the absence of cancer, if the symptoms under consideration have lasted for several months. The application of this point in physical diagnosis is illustrated by the clinical histories of six cases.

British Medical Journal, April 2, 1904.

Abstract of the Arris and Gale Lecture on the Chemistry of the Urine in Diseases of the Pancreas.—P. J. Cammidge gives the results of observations of over 300 specimens of urine. He says that in view of the fact that inflammation of the pancreas is in a considerable number of cases associated with more or less jaundice, it is not surprising to find that bile pigments were discovered in 60 per cent. of the urines examined. In some only a faint trace was detected with difficulty, while in others there was a very large quantity. All the specimens but one derived from cases of malignant disease of the pancreas showed a considerable amount of bile in the urine. No special significance can be attached to the quantity present, as in many cases with chronic catarrh the urine is as deeply colored as it is in most cases of malignant disease. The removal of any obstruction of the common duct that may exist is generally followed very shortly by the disappearance of bile from the urine, but in a few cases in which the condition is of long standing, bile pigments may be found, although in much diminished quantity, several weeks, or even months, after the operation.

A Clinical Lecture on the Detection of Early Tubercle in the Lungs.—Isambard Owen emphasizes the fact that the condition of time is all important in this disease. Every month during which active tuberculous disease remains undetected and untreated lessens appreciably the prospect of recovery. He thinks that the use of the term "stage" in reference to cases of pulmonary tubercle is incorrect and misleading. Pulmonary tuberculosis, in most of its ordinary forms, is a disease of essentially intermittent or remittent character. This is not always so, however. Except in cases in which early hæmoptysis draws attention to the lungs it is doubtful if we often really see the initial attack at all. The writer, after a cursory inspection, makes a thorough stethoscopic exploration of the upper parts of the lung. He follows this up with percussion and with a more detailed inspection and palpation. The pitch of the harsh or tubular breathing heard in early tubercle of the apex is nearly always low. This "pitch" is always a mere "noise," compounded of vibrations of indefinitely various lengths. The breath sounds on the sides should be compared for intensity and rhythm as well as for character. Genuine broncophony without associated change in the breath sounds is very rarely met with. On account of the normal excess in vocal resonance of the right chest as compared with the left, great caution must be used in drawing conclusions from an apparent increase of voice sound at the right apex, unless its character be changed or other signs occur. The value of vocal fremitus in the diagnosis of early lesions is practically nil. To percuss the apices satisfactorily, it is desirable to have the patient standing before one. The results of percussion in many cases appear to correspond but ill with those of auscultation. Both light and deep percussion should be practised and their results compared. Before deciding on any question of moist sound, the patient should be made to cough. The cough brings out the moist sound that indicates alveolar exudation, and it eliminates moist sounds due merely to bronchial catarrh. It must be remembered that in a small number of cases the lesion is purely bronchopneumonic from the outset. The absence of bacilli is not absolute proof that there is no active lesion, and their presence, unless in large numbers, does not exclude the possibility of the lesion being at the time quiescent and mainly fibrous. Neither physical signs nor bacteriological results must blind one to the importance of symptoms in cases of doubtful diagnosis. A daily rise of temperature and a progressive loss of weight, otherwise unaccounted for, are most important symptoms. "Creaking" rhonchus in the adult should always convey a strong suspicion of tubercle. If, in addition, the inspiration should bring out sharp clicks, or even small râles of a higher pitch than is found over the rest of the lung, the proof is almost formal. These statements apply to the adult only, and practically to the elderly subject.

British Medical Journal, April 9, 1904.

Papilliferous Cyst from an Axillary Sudoriparous Gland.—H. Betham Robinson had charge of this case. The patient was a woman aged twenty-two years, who had noticed a lump growing in her armpit for two years. After removal, section showed it to be a skin cyst, consisting of one large cavity containing a thin watery fluid; the lining was in general smooth, but over an area the size of a sixpence, soft papillary growths were attached. The papillary processes show a many-layered epithelium, the surface cells being swollen and vacuolated, as is often seen in secreting glands. The appearances suggest an origin from that part of the duct between the epidermis and the coiled tube. This class of cyst is very rare. The writer had another almost identical case in a little girl aged thirteen.

On the Action of the Blood Serum from Cases of Acute Mental Disorder on B. Coli Communis.—Alice V. Johnson and Edwin Goodall conclude: (1) In 50 per cent. of the total cases of acute insanity examined, there was agglutination, whereas this was present in only 15.5 per cent. of the controls. (2) The agglutination was partial in the great majority of the cases (39 per cent.). (3) In those forms of the disease in which the cases were sufficiently numerous to permit of percentages being taken (mania and melancholia), the preponderance of partial over good agglutination was also obvious. (4) The percentage of agglutination (good and partial) was greater (58.5) in the cases of melancholia than in those of mania (45.2). (5) The percentage of good agglutination was greater in melancholia than in mania. (6) Even when the disease is quite recent in duration there is as often as not a failure to agglutinate.

Experimental Nephritis Followed by Decapsulation of the Kidney.—I. Walker Hall and G. Herxheimer define renal decapsulation as consisting of the removal of a part of the capsule, or of the entire capsule, with more or less laceration of the cortical tubules, of hemorrhage, and of the exposure of a "raw" absorptive surface. The removal of the capsule accelerates the absorption of any local toxins. In eight to fourteen days after renal decapsulation in animals in which degenerative nephritis has been induced, the kidney is covered by a thick, strong connective tissue capsule, and the hemorrhages and marked necrosis are replaced by cellular tissue, which in some instances is connected with the capsule, and which persists after the nephritic changes have resolved. When the capsule is removed in the first instance, the normal passage of capillaries from the capsule into the superficial areas of the cortex will be broken; if this is afterward fully regained, it is all that may be expected. From the anatomic standpoint yielded by their experiments and by those previously reported, the writers do not think that decapsulation appears to offer any advantages. If there is no anatomical basis for the operation in acute degenerative nephritis, it is impossible

that in chronic nephritis the capsular changes will be less marked. The simpler veni-puncture relieves tension and promotes renal functions. Boncz-Osmolowsky has found in his experiments that six days after decapsulation the leucocytes and connective tissue were increased between the tubules and the cells of the superficial tubules showed granular changes in the protoplasm. Twelve days after the operation there was atrophy of renal cells. He did not observe any new formation of blood-vessels in the reformed capsules.

Berliner klinische Wochenschrift, March 28, 1904.

Gonorrhœa in the Puerperal State.—Martin reports on twelve cases in which gonorrhœa was present during the puerperium, the diagnosis being established by the demonstration of the organism and in most of the instances by its cultivation. Four of the patients had no elevation of temperature and of the others six did not exhibit any rise till late in the puerperium. In all cases the affection ran a benign course and no tenderness of the uterus or evidences of perimetritis or parametritis were observed. Two of the patients have since become pregnant again and one of these has been confined without complications. Two of the infants developed gonorrhœal ophthalmia. The series proves that conception can take place during the course of a chronic gonorrhœa and that the pregnancy can go on to term without interruption.

The Diagnosis of Gastric Carcinoma.—Sigel has tried some of the methods that have lately been recommended as giving early diagnostic signs of carcinoma of the stomach in order to test their reliability. The first of these is the tryptophan reaction which was described by Erdmann and Winternitz, and consists in the production of a violet color when chlorine or bromine is brought into contact with proteinochron. This is an albuminous body found in the test-meals in cases of carcinoma. The method proved very unreliable in the author's hands, as the reaction was present in only two out of fifteen cases of carcinoma examined and was also positive in a case of ulcer. Salomon tests the amount of albumen and nitrogen present in the washings after the patient has been for a day on albumen-free diet and has had the stomach washed out several times. If the albumen is high in amount by the Esbach method and the nitrogen exceeds 20 mg. in 100 c.c. of the fluid, carcinoma is said to be present, but the author's results in twenty cases show that though of value in special instances the method is not infallible. Gluzinski, washes out the fasting stomach in the morning and then gives two test meals through the day in an endeavor to detect the change from an acid to a catarrhal gastritis, which occurs when carcinoma begins in an old ulcer. In eight cases of ulcer tested in this way the results pointed toward benignancy, while in four out of five cases of carcinoma the diagnosis was corroborated by the method. The author considers that considerable reliance may be placed on the procedure, and that in suspected carcinomas if HCl is constantly present under these conditions a diagnosis of non-malignancy may be made even if many other features point toward the more serious disease. The estimation of the fatty acids in the urine advocated by several authors did not give favorable results. He concludes that these various methods may often be of assistance, but that a broad consideration of all the clinical features is always necessary, and that purely chemical precedures cannot be relied upon to clear a doubtful complex of symptoms.

Münchener medizinische Wochenschrift, March 29, 1904.

The Injection Treatment of Gonorrhœa.—Lucke says that the compressor muscle offers only an incomplete barrier between the anterior and posterior urethra, and that this fact must be taken into account in treating urethritis by means of injections. There is a difference in the effectiveness of the compressor muscle in first infections and in later attacks. With first infections it may be assumed that the barrier is to be relied on for the first fourteen days, and the effort must be made to clear the superficial layers of the mucosa of germs during this time. When this has been accomplished it is usually possible with care to prevent extension posteriorly, and it may be said that first infections are satisfactorily to be treated by Neisser's method. With those who have already had other attacks, however, the compressor muscle is not to be depended on, and pressure injections should never be made until the anterior urethra has been freed from organisms by catheter irrigation, or by Janet's method. After this the injections may be employed. First infections that do not come under observation until the third week are to be treated like multiple infections. Examination with the urethroscope gives the best criterion as to complete cure.

The Relations between Laryngeal and Pulmonary Tuberculosis.—Frese discusses the various arguments which advocates of the local infection theory and of infection through the blood or lymphatics in laryngeal tuberculosis put forward, and details experiments made on dogs to settle the question. The laryngeal mucous membrane of the animals was subjected to either mechanical or chemical irritation, and then tuberculous sputum or pure cultures were rubbed on the surface. Five drops were used, and in spite of the resistance of these animals to tuberculosis, in one case typical tuberculous laryngitis was produced. A few tubercles were also found in the lungs and spleen thirty-eight days after the inoculation. The laryngeal mucous membrane was intact over the tuberculous lesions, no ulceration having resulted. From this observation, and from the theoretical considerations the author believes that tuberculous laryngitis is the result of sputum infection, and except in cases of general miliary tuberculosis is not to be ascribed to dissemination through the blood or lymphatics.

Isolation in the Treatment of the Insane.—Dieckhoff says that the treatment of the insane has passed through several successive phases; first, the abolition of the chains and barbarities that prevailed prior to the reforms instituted by Pinel, then the no-restraint system, and now the effort to abolish even the feature of isolation. The effect of the latter is injurious in several directions. It is accomplished only under constant physical restraint; it encourages maniacal outbreaks and does not produce the desired calming effect. In order to replace it several measures are employed. Narcotics do valuable service, though there is a limit to the point to which it is wise to push their administration. Rest in bed is a natural consequence of their use, and has most beneficial results. Prolonged hot bathing, extending over periods of hours, days, and even weeks is a most valuable sedative, and is never injurious; moist packs are useful, but if too long continued are apt to be followed by collapse. Of the greatest service are occupation out of doors and separation. By the latter is meant segregation of the patient but without the element of forcible restraint, as the doors are removed from the cells, or they are not locked. The newer system is somewhat difficult of application, but its consistent use in numerous institutions proves that it is *possible* to dispense with isolation in its older sense and therefore it *should* be dispensed with. Requisite are a large number of attendants, who must be of somewhat higher type than those employed under the old plan, and a careful medical supervision to recognize the first signs of impending outbreaks of violent nature.

French and Italian Journals.

Infectious Subglottic Œdema.—Deguy and Detoc report the case of an infant of nine months. The child had been suffering for eight days with a slight cough. For twenty-four hours before entering the hospital respiratory difficulty had peen progressive. The dyspnœa became intense, but there were no signs of diphtheria. Intubation became necessary. In performing this operation, marked œdema of the arytenoepiglottic folds was noted, but no retropharyngeal abscess. The dyspnœa persisted, however, in spite of the treatment, and within half an hour became so intense that the tube was suddenly ejected. Tracheotomy was practised on the spot. The dyspnœa then disappeared, and the respiration returned to its regular rhythm. On the next day the subglottic œdema persisted, the temperature became elevated, the urine showed the presence of albumin, and the dyspnœa reappeared. There were no signs of bronchopneumonia. Four days after its entrance to the hospital, the child died. Autopsy showed œdema of the arytenoepiglottic folds and of the superior vocal cords; tracheobronchitis with ulcerations, intense pulmonary congestion without any foci of bronchopneumonia. Examination of the blood taken from the heart immediately after death, and the microscopic study of the different organs, showed everywhere the existence of a yellow staphylococcus, which, inoculated into animals, proved to be very virulent, causing œdema.—*Le Progrès Médical*, March 12, 1904.

Contribution to the Study of Arguillulosis Intestinale.—Alberico Testi has made a study of the conditions under which the intestine is infected by these parasites. We are well acquainted with the development of the trichina in the intestine, and its passage by the lymphatics or the blood into the organism, to localize itself in the muscles. Tessier saw in the blood of a patient the larvæ of the parasite of trichinosis. The penetration of the larva may be assisted by a lesion of the intestinal mucosa. Ulcerative lesions are produced in various ways—for instance, by the presence of nematodes and other inhabitants of the intestine, such as lumbricoids. The author's own case indicates that to obtain nutrition the arguillulosis may enter the mucosa and produce grave lesions which may end in secondary septicæmia and death. This procedure distinguishes them from ankylostoma, which has quite other attributes. Ankylostoma produces only small superficial

hemorrhages, while arguillulosis may produce very severe deep lesions of the intestinal wall, the glands and the lymphatics. It was impossible to discover how the anguillulosi entered the intestine; the diet, mode of life, etc., of the patient did not differ from that of those persons living near her. The author believes that cases of arguillulosis infection are much more common in Italy than is generally recognized, and that the larvæ are communicated to those who work on the land by drinking water from the streams, or by eating green vegetables.—*Rivista Critica di Clinica Medicina*, February 20, 1904.

The True Value of the Objections Advanced against the Intramuscular Injection of Calomel in the Treatment of Syphilis.—A. Scarenzio has found calomel used hypodermically most successful in the very obstinate cases that resist all other forms of mercurial treatment. He recommends using calomel prepared from the vapor, because it does not clog the syringe, using oil of vaselin as medium, and making the menstruum perfectly aseptic. The Pravaz syringe should be used, made of ebonite and with a long needle that is not too small. The preferred location for the injection is the upper part of the gluteal muscles, a little above the great trochanter, at the beginning of the sacrococcygeal fold. It is to be recommended in phagedenic syphiloma of the tongue, malignant syphilides with early ulceration, tertiary sclerotic glossitis, severe laryngitis, rebellious secondary lesions of the tongue, and old gummata of the nervous system that resist all treatment. He has not found it to have bad results in cases in which proper dosage and technique were used. No marked pain was produced at the site of puncture, nor has he observed severe stomatitis, diarrhœa or embolic manifestations following its use.—*Gazzetta Medica Lombarda*, February 22, 1904.

The American Journal of the Medical Sciences, March, 1904.

Hæmolymph Nodes.—Hughes Dayton concludes that the histological and experimental evidence is strongly indicative of the existence of the hæmolymph node as an organ *sui generis*. In the light of our present knowledge the chief practical point, however, is to recognize the capacity for phagocytic destruction of red blood cells which is possessed to a high degree by certain lymphoid structures, rather than to dwell upon the individuality of the hæmolymph node. The occurrence of transition forms from the node containing blood sinuses only to that with sinuses containing lymph alone renders a strict classification impossible. For practical purposes Warthin's grouping of cell varieties under the heading of hæmolymph nodes appears eminently satisfactory.

A Study of the Caloric Needs of Premature Infants.—John Lovett Morse believes, from his study of this subject, that the caloric need of premature infants is relatively greater than that of full-term infants. This greater need is due in part to the small size and comparatively large surface area of premature infants, which cause them to lose heat faster than do larger, full-term infants, and partly to the incomplete development of their digestive powers, on account of which they utilize a relatively smaller proportion of the caloric value of the food ingested. This conclusion emphasizes the importance of protecting premature infants against loss of heat and of providing for them a food which will throw the least work on the partly developed digestive powers.

Multiple Sarcoma.—Thomas A. Clayton considers here the multiple sarcomatous growths in the skin and subcutaneous tissue, excluding that class of tumors characterised by lymphoid cells. As to the etiology of sarcoma, whether single or multiple, practically nothing is known. It may follow an injury or may take its origin from old scar-tissue, or there may be no discoverable cause. The parent tumor in this variety of sarcoma is not infrequently a pigmented mole which suddenly becomes malignant. The usual cause for this change is an accidental injury or friction from the clothing. The symptoms are not distinctive. The blood shows nothing but the conditions found in any severe secondary anæmia. The diagnosis is simple in a fully developed case. In the early cases it is not so easy. The most satisfactory method of diagnosis is to remove one of the smaller nodules for microscopical examination. But operations upon sarcomata are often followed by rapid and more malignant recurrence. If the skin has been involved, the growth is almost sure to recur at the original site, but if subcutaneous, the danger is much less. The question of operation is one which requires careful consideration. As to drugs, arsenic is the only remedy which has proven of any value.

Three Cases of Pernicious Anæmia, with a Description of the Pathological Changes Found in the Spinal Cord.—Robert Reuling describes these cases, one by one. In the first case, in every specimen examined, there was seen a narrow strip of degeneration in both the column of Goll and that of Burdach, most marked in the former in most sections. The degeneration was most apparent in the lower cervical and upper dorsal regions. In the Van Gieson specimens it was clearly shown that these degenerated fibers had lost their myelin sheaths, and very few axis-cylinders could be made out in the degenerated areas. The remainder of the cord was absolutely normal. The same degeneration was apparent as far down as the upper sacral cord. In the second case the spinal symptoms seemed to precede the onset of the anæmia. In all sections except those from the very lower dorsal, and the sacral regions, a well-marked degeneration, involving almost the entire posterior tract of fibers, including the columns of Goll and Burdach, was seen. The change was most pronounced in the upper dorsal and lower cervical regions. A number of nerve fibers of both right and left lateral columns had degenerated. In the third case the only change from the normal were several small circumscribed areas of degeneration limited to the anterior parts of the cord. This degeneration was due to small hemorrhages into the cord substance.

Tuberculous Stricture of the Ascending Colon, with Sudden Total Obstruction of the Bowel; Perforation of the Intestine; Removal of the Cæcum and Half the Ascending Colon; Recovery.—Thomas S. Cullen reports this case of a patient twenty-four years old, who had practically no symptoms until about five hours before operation, and then there was moderate pain over the appendix, accompanied by rigidity of the right rectus. Examination of the blood showed a total absence of eosinophiles. The only way in which the writer can account for the lack of symptoms is that for some reason there occurred an acute contraction of the stricture, which, up to this time, had permitted the free passage of fæces. The possible existence of such a condition supplies another indication for early operation whenever trouble exists in the appendiceal region. Already peritonitis had developed, although the symptoms had existed for so short a time; and had there been a little delay, there would have been scant chance of saving the patient. After the appendix was removed and the pus wiped from the pelvis, the abdominal cavity appeared normal. The right renal pocket was exposed, however, and some dark fluid escaped. A perforation in the ascending colon was then discovered. Where there is a free accumulation of fluid in the region of the appendix, by gravity it will travel down into the right renal fossa. The ascending colon was drawn out and total obstruction was found a short distance above the ileocæcal valve. The lower third of the ascending colon, the cæcum, and a small part of the ileum were removed. An end-to-end union was made on account of lateral tension.

An Experimental Study of the Relation of Cells with Eosinophile Granulation to Infection with an Animal Parasite (Trichina Spiralis).—Eugene L. Opie declares that the administration of trichina spiralis to the guinea-pig causes an increase of the eosinophile leucocytes in the blood, comparable to that which accompanies human infection. There is no constant alteration of the number of these cells until the end of the second week after infection, when their relative and absolute number rapidly increases, and reaches a maximum at the end of the third week. At this time embryonic trichinæ are in process of transmission from the intestinal mucosa by way of the lymphatic vessels and the blood through the lungs to the muscular system. Eosinophile cells accumulate in the mesenteric lymphatic glands and in the lungs and form foci which resemble small abscesses in which polynuclear leucocytes are replaced by eosinophile cells. These cells are provided with polymorphous nuclei and do not differ from the eosinophile leucocytes of the circulating blood. Accumulation of eosinophile cells in the mesenteric lymphatic glands and in the lungs is explained by the transmission of the embryonic parasite through these organs. Increase of eosinophile cells in the blood and in other organs is accompanied by characteristic changes in the bone-marrow. The fat is diminished in amount, and cellular elements replace it. Cells with eosinophile granulation are present in immense number, and particularly numerous are the eosinophile myelocytes, cells peculiar to the bone-marrow, while such cells, undergoing mitotic division, are more numerous than usual. The bone-marrow is the seat of multiplication of the eosinophile leucocytes. The number of eosinophile leucocytes in the blood always diminishes before death, so that the proportion usually becomes less than 1 per cent. Infection with a very large number of trichinæ causes a rapid diminution of the number of eosinophile leucocytes, and is quickly fatal. The eosinophile cells of the bone-marrow exhibit degenerative changes, of which nuclear fragmentation is most characteristic. Similar changes may affect the eosinophile cells of the intestinal mucosa and of the mesenteric lymph glands. Mild infection stimulates the eosinophile cells to active multiplication, but severe infection causes their destruction.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON ORTHOPEDIC SURGERY.

Meeting Held February 19, 1904.

HOMER GIBNEY, M.D., CHAIRMAN.

Arthropathies of Locomotor Ataxia.—Dr. GEORGE R. ELLIOTT presented patients with this condition. In the first patient the left knee was the only joint affected, showing *genu inversum* and not to be confounded with primary *genu valgum*. There was a certain enlargement of the head of the tibia, œdema about the knee-joint, and enlargement of the leg and thigh. The left leg and thigh measured one inch more than the right. The chief subjective symptom was metatarsal pain. Four operations have failed to relieve this troublesome symptom.

The second patient was a man about fifty-seven years old, confined to a wheel chair and bed. The joints involved were the small joints of the fingers, chiefly the first phalangeal joints. These deformities were globular in shape, painless and devoid of swelling, and had been so from the beginning. The patient in his wheel chair with overcoat on, placed the heel of both feet behind his head, demonstrating the muscular hypotonia common in locomotor ataxia.

He further presented a cast of the hand of a third patient who was unable to be moved. The cast showed very marked globular swellings of the phalangeal joints. He also had a very marked arthropathy of the left shoulder, so badly involved that he could dislocate the joint at will. The head of the bone was markedly enlarged, the acetabulum was filled up, and there was destruction of the capsule and ligaments—all painless from the beginning.

Dr. V. P. GIBNEY said he thought the laxity of muscles in case No. 2 very interesting, and wanted to know whether that was a common feature of the disease. He thought it extraordinary to see a patient as old as this man, with ligaments so relaxed as to enable him to put his legs over the back of his neck. In those cases he had seen, the laxity of ligaments was in the ankles and knees. The other case was interesting on account of the neuralgia in the internal plantar, and failure to get relief after section of the nerve, but he presumed that the tabes from which the man suffered, rather ruled it out as a case of metatarsalgia.

Dr. R. SAYRE said in many cases the relaxation affects the joints of knees and ankles as well. He had had many cases in which the patients could walk around comfortably with lateral support on knees, when they were incapable of standing without this support, the ligaments being so relaxed. In these cases the joints were prone to luxate.

Dr. BREWER said he was interested in the case reported. He had treated a similar case: A neurotic boy who complained of pain in the metatarsal joint of the great toe. He could not step or walk. There was an extremely tender point over the joint, which was a little thickened and reddened. He had worn a badly fitting shoe, which perhaps caused slight deviation of the toe. The joint was opened and found to be healthy. A little piece of bone was taken away, and the pain was relieved. A return of acute pain occurred, which was relieved by the application of the cautery. This relief continued for a number of weeks, but the pain returned, so intense the boy could do nothing. He was in an hysterical, nervous state. He was seen by Dr. Blake, who took out about one inch of the internal plantar nerve, affording relief. Three months later he again operated and took out the whole of the nerve, which presented a small neurofibroma near its origin. The pain came back after a while and the boy underwent a fourth operation, this time Dr. Bull operating. In about three months there was a fifth operation, the result of which was unknown. Dr. Brewer would like more light on the subject of these cases. He thought it rather common to find such laxity of the hip ligaments from non-use.

Dr. DANA said he could only confirm Dr. Elliott's statement that there is this relaxation, very marked, in most cases of arthropathies, usually associated with atrophy of the head of the bone. He was interested in hearing the remarks about splints for the joints. He thought it a mistake always to put splints on tabetic joints. He cited a case in illustration.

Dr. SAYRE said that in marked relaxation of ligaments it was sometimes quite possible to slip the femur on the tibia. When the patient was upright and moved in any direction, there was danger of complete luxation of the joint, and possible rupture of the skin as well by constant violent slips. He had seen those who were incapacitated for going about except with two crutches, who, when properly fitted with apparatus, could walk without a cane. There was sufficient muscular power and sufficient coordination of the muscles to move the legs in an anteroposterior direction, if something was put on to limit the lateral deviation.

Scurvy Simulating Pott's Disease.—Dr. HOMER GIBNEY presented a child of twenty months from the Dispensary of New York Hospital referred as case of lumbar Pott's disease. No disease of the spine was, however, found, but a very marked scorbutic condition in addition to a pronounced general rachitis. The scorbutus responded quickly to treatment, and the long posterior rachitic spinal curvature is yielding to a perfectly fitted frame on which the child is placed and mother instructed as to its management.

Acute Infectious Osteomyelitis of the Spine and Acute Suppurative Perimeningitis.—Dr. J. RAMSAY HUNT read this paper. (See p. 641)

Dr. DANA said he had only seen one case such as Dr. Hunt reported, and could add nothing to the subject. He only rose to express his gratification at the clear and convincing way the matter had been presented. He thought Dr. Hunt's view that perimeningitis is always secondary, correct.

Dr. BREWER said he had seen only two such cases, both unrecognized at the time he first saw them. He had been looking for a comprehensive paper giving fuller statistics than could be found in abstracts from foreign literature, and such a paper had been read by Dr. Hunt. He thought it most valuable from a surgical point of view. In each of Dr. Brewer's cases there was a perirenal abscess. The pus was found to issue from diseased vertebral bodies. In both cases there was extreme sepsis. He supposed at first that the trouble came from the kidney. After exploring the kidney and finding it normal, he made a small opening in the psoas, then into the vertebral column and removed the sequestrum. The first patient died in a week or ten days. After death an autopsy revealed a very extensive process. In the second case, a man had chills and fever, and complained of pain in the back, which had been relieved for a number of days before Dr. Brewer saw him; and with the relief of pain, there was the formation of a large lumbar indurated mass. This was opened. At the first operation a quart of pus was evacuated. The septic symptoms abated, but there was no closure of the sinus. A second operation was done to remove a supposed diseased and suppurating kidney. By making a large incision, the region of the kidney was exposed, and found to be normal. The psoas was filled with pus: also a focus in the body of the vertebra. Dr. Brewer said he had another case but was not sure it was primary septic osteomyelitis. It occurred in the arch. It was an old case operated on before Dr. Brewer saw it. He simply provided better drainage. He thought these cases should be diagnosed early, and that we should be on the lookout for them. The rate of mortality was high. The vertebral bodies were inaccessible, and required prompt treatment.

Dr. V. GIBNEY said those who had been handling

vertebræ for a great many years would feel especially in sympathy with a differential diagnosis. In regard to prognosis and analogy of osteomyelitis of the vertebræ and of the hip, when Mr. Smith of London began to report cases, and Mr. McNamara followed, there was frightful mortality. As they were recognized earlier, the mortality was much lessened, because their acute infectious nature was understood and prompt measures were taken to secure relief. In place of dangled hips with a few half-opened abscesses, we now have much better hips, going at once to the focus of disease removing sometimes the head lying loose in the cavity, fixing the limb in good position, draining well and getting prompt relief and pretty stable hips. During the last year or two, when so much had been said and observed about congenital hips, he had found cases said to be such hips, with one or two tell-tale abscesses on the outer side of the thigh with history of acute abscess which had opened, when the child began to walk lame. A patient was brought to him recently from a long distance, said to be suffering from congenital dislocation. The speaker saw a cicatrix on the inner side of the thigh. He was told that at nine months the child had had an acute attack of hip trouble, the abscess opening and soon healing. When the child began to walk, no attention was paid to the hip. There was an inch and a half shortening, and the case was labeled as one of congenital dislocation of the hip. In regard to pachymeningitis, etc., he was reminded of a neurological experience—Dr. Putzell read a paper when we were finding a number of those cases, and the speaker had put on record two or three cases of peripachymeningitis hypertrophica cervicalis not acute. Those cases would now simply be eliminated, if we had to recognize the disease as osteomyelitis. We had stopped talking about acute suppurative periostitis and acute peripheral osteitis. Eight or ten years ago Dr. McNamara showed the speaker specimens in Westminster Hospital, declaring it was general osteomyelitis, and could not fairly be called periostitis.

Dr. SAYRE said he could only add his voice to those who had preceded him. He thought, with Dr. Gibney, that the cases were recognized and operated on promptly now, and compared with the mortality of the past, there was a gratifying number of recoveries. He had had two cases showing acute suppuration, and had opened, drained, and planned—under such treatment the majority of cases recovered as had those he mentioned. The difficulty, however, was in recognizing the cases in which the foci were deep-seated, and operating upon them promptly enough to give relief.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, March 24, 1904.

DR. A. PALMER DUDLEY IN THE CHAIR.

Recurrent Tubal Pregnancy.—Dr. PHILANDER A. HARRIS presented this specimen and reported the case of a negress, twenty-six years old, upon whom he first operated May 20. The abdomen was found to be filled with blood and clots, and from it was removed a fœtus about ten inches in length. Before operation 425 c.c. of normal salt solution was thrown into the veins and, after the operation, 650 c.c. more. The patient made a good recovery and menstruated every four weeks after. It was comparatively painless since recovery from her previous tubal pregnancy, until February 18, when the appearance of blood was attended with severe pains in the hypogastric region, more especially upon the left side. Pains recurred almost daily. On March 22 she was seized with a severe pain in the left lumbar region, and then was sent to the hospital. Physical examination showed the cervix to be rather soft and velvety and the uterus fixed in its position with a tumor above and to its left. On March 23 abdominal section was performed. A pint or more of blood was found in the abdominal cavity, and some clots partly organized and very adherent to the omentum and intestines. The left tube was about 8 inches long, 1¾ inches in diameter, closed at the ostium abdominale, and was believed to contain the product of an interrupted if not progressive pregnancy. The tube was exsected, closing the chasm in the uterus with sutures. The isthmian portion of the tube on the right side was larger, harder, nodulated, and altered in character and appearance since the operation ten months previous. This, too, was exsected. At the last meeting of the Section he stated that he had met with five women in whom tubal pregnancy had recurred. To that he now added another, making altogether six cases of this class.

Hæmatoma of Both Ovaries.—Dr. PHILANDER A. HARRIS presented this specimen, removed from a woman thirty-nine years old. He said that apoplexy or hæmatoma of the ovary of such magnitude as the specimen presented was certainly a very frequent occurrence. It had been asserted that one effect of chronic apoplexy of the ovary was to destroy the stroma of the ovary. The case which he presented had the condition of hæmatoma in both ovaries, and it had probably existed in both ovaries for many years without inducing the menopause. For the past ten years or so the duration of every menstruation had been three or four days, while in her earlier life it lasted a full week. The shell, which was all that remained of her right ovary, had not only been sufficient to insure the continuance of menstruation, but the duration of the flow had been somewhat lengthened and its quantity increased. He had since incised and cauterized its cavity. The left ovary, which had been the seat of a hæmatoma, was removed.

Dermoid Cyst.—Dr. PHILANDER A. HARRIS presented this specimen. The cystic ovarian tumor was on the left side and was found to contain the usual greasy material of dermoid cysts, also a ball of long hair, half as large as one's fist, and one tooth growing from its wall. The ball of hair was threaded through its center by a string of tissue about 2 mms. in diameter, either end of which was attached to opposite sides of the cyst wall.

Extensive Primary Peritoneal Tuberculosis; Tuberculous Omentum, Fallopian Tubes, and Ovaries.—Dr. HERMANN J. BOLDT presented these specimens, which he had removed from a patient forty-two years old. Her present illness began eight months ago with pain in the abdomen and increase in its side. She had very obstinate constipation. She lost much flesh and strength. The abdomen was greatly distended with ascitis. On opening the abdomen a large quantity of dark gray-greenish fluid was evacuated, as well as numerous masses of gelatinous material. A smooth tumor wall presented itself, which was proven to be of pyogenic membrane, enclosing the entire viscera. Upon opening this sac intestines came into view, and they were found to be thickly studded with small tuberculous nodules, and the bowels throughout intimately adherent to each other. These adhesions were broken up and much bleeding occurred. The brittleness of the structures was so that no ligatures could be applied and tight tamponading became necessary. The entire omentum was rolled up in a tumor-like mass above the transverse colon and was amputated with the Paquelin cautery. The patient was making a smooth recovery. No tubercle bacilli were found in the sputum. He said the peritoneum was undoubtedly primarily affected.

Inflammation about a Meckel's Diverticulum Resembling an Appendicitis.—Dr. BOLDT presented this specimen. At operation, when looking for the appendix, there was brought up into the wound what was thought to be an inflamed appendix, but which proved to be a large diverticulum, so closely resembling it that it could not have been distinguished from one had it not been for the small intestine. The appendix itself was found to be normal.

Unusually Large Suppurating Tuberculous Tuboovarian Tumor Removed with the Uterus; Tuberculous Peritonitis; Recovery.—Dr. BOLDT presented these specimens. The

left lower abdomen was more prominent than the opposite side, and was filled with a tumor which reached above the level of the umbilicus. It was very adherent and somewhat sensitive to pressure. Whether the tumor was the primary tuberculous condition, or whether its tuberculous change was secondary to the tuberculous peritonitis was a question not determined. The sac wall measured from 1 to 1½ cms.

Vaginal Hysterectomy for Uncontrollable Uterine Hemorrhage.—Dr. BOLDT reported this case. Extirpation of the organs was resorted to because, with such frequent recurrences of adenomatous proliferation of the endometrium, practical experience had shown that malignant disease was the usual outcome.

Extensive Rupture of a Tubal Pregnancy.—Dr. BOLDT reported the case of a woman, twenty-six years old, who was supposed to be pregnant ten weeks. Rupture took place about five hours after consultation, and she was operated on immediately while pulseless and in collapse. The surgical work required scarcely five minutes and the bleeding tube was secured in a fraction of a minute, but, despite all efforts, she died.

Retroperitoneal Abscess Simulating a Pyonephrosis—Dr. A. STURMDORF presented a kidney removed from a woman twenty-six years old. She had had two severe attacks of suppurative appendicitis, which were treated simply by cutaneous incision by the attending physician. When first seen by him last May there was pain and tenderness in the right inguinal region, and examination showed suppurative disease in the right side of the pelvis. The operation revealed a long sclerosed appendix, whose tip was adherent to the abdominal wall, and there was an abscess involving the right tube and ovary. Some months later she returned in a septic condition, and operation then revealed what was supposed to be a very large suppurating kidney, and then pus appeared in the urine for the first time. The ureter was evidently occluded and could not be made patulous. The functional activity of the other kidney having been determined, the injured kidney was extirpated. What had closely simulated a pyonephrosis proved to be nothing more than a retroperitoneal abscess, surrounding and involving the perirenal connective tissue.

The Treatment of Post-operative Peritonitis.—Dr. EGBERT H. GRANDIN presented this paper. He said that the initial treatment of post-operative peritonitis was summed up in the one word prophylaxis. This prophylactic treatment consisted of attention to the following points: Absolute asepsis in the operating room; the avoidance of germicides, such as bichloride, during the operation; the handling of intestines, and the exposure of omentum as little as possible; the covering of raw surfaces with peritoneal flaps as far as possible, and where this was impossible the protection of such surfaces by sterile gauze.

In any case in which the presence of pus was suspected before operating or in which it seemed probable that pus might form, ten grains of calomel combined with twenty grains of bicarbonate of soda should be administered three hours before operation to provide for catharsis afterward, thus avoiding futile attempts at such administration in the presence of an irritable stomach. If after such precautions peritonitis developed he distinguished three types: The paretic or pseudo-peritonitic; the inflammatory; the septic. Not infrequently after abdominal section, the belly became gradually tympanitic, the stomach rejected food, the pulse and temperature were slightly elevated, and the operator, in despair, proceeded to dose the patient with a multiplicity of drugs, with the result that the patient died. This type of peritonitis, viewed from the standpoint of the clinician, he termed spastic or paretic. In these cases he employed only one drug, either atropine or hydrobromate of hyoscin, in full doses, hypodermically to the physiological extent, with the result that the spasm of the bowel relaxed and the patient recovered.

In the inflammatory type of peritonitis the temperature and pulse began to rise three or four days after an aseptic abdominal section, and this to the vital point. The bowels might or might not respond, the stomach was intolerant of food and medication. Here the operator, who had administered calomel before operating, was fortunate. In such cases we had to differentiate between general and pelvic peritonitis, and if it became apparent that we were dealing with an inflammatory condition of the peritoneum it was evident that what this organ needed was rest, not the spur. To the rest we might add with advantage the ice-bag to the abdomen, washing out the stomach, and rectal feeding. Fordyce Barker taught the free exhibition of codeine under such circumstances, as this drug neither paralyzed peristalsis nor upset the stomach. The case should be carefully watched, and if pus formed locally or in the pelvis it should be attacked under well-recognized surgical rules. In septic peritonitis also that operator was fortunate who had the calomel in the stomach of his patient before the operation. He employed the term septic generically, as the bacteriologist afforded no definite help as to the exact germ or toxin that we were dealing with. This form of peritonitis was characterized by rapid pulse and respiration and low temperature. The belly might or might not be tympanitic, the stomach was apt to be intolerant, the bowels were apt to be loose and the kidneys to be torpid. In these cases we were dealing with a deep toxæmia, and the best we could do was to institute a sustaining treatment, in the hope that Nature might throw off the toxins or the products of the toxins. He suggested toning up the heart's action by means of alcohol and of strychnine. When the kidneys were inefficient he used digitalis. He threw plenty of salt into the circulation by means of the veins or the rectum or through the medium of the skin, taking the hypothetical view that we were thus diluting the toxins. If pus could form in the pelvis or abdomen, open. The injection of formalin into the veins, the insinuation through posterior section of iodine into the system, etc., had yielded no better results than the sustaining methods. In regard to local septic peritonitis he could show as good results from opening the cul-de-sac and impacting plain sterile gauze as those recently heralded from the use of a specially prepared iodoform gauze.

The Treatment of Post-puerperal Peritonitis.—Dr. ROBERT MURRAY said that this, like all forms of peritonitis, was due to sepsis, or the introduction of virulent bacteria at the time of confinement, and should be differentiated from the other attacks of peritonitis. There was not usually one organ involved, but the uterus, the adnexa, the vagina and external parts, all might be involved in the septic process. It was important to note that, in such cases, the condition was not autogenetic, but the poison was introduced by the hands of the surgeon, nurse, or some attendant. The virulence of the course of peritonitis was to be determined by the particular bacteria causing the infection and also, in a measure, by the methods of their entrance into the system.

He said that puerperal peritonitis was only one of the septic puerperal diseases, and yet it was the one which, in greater or less measure, was a complication of all of them. Confining himself to peritonitis, clinically peritonitis in the puerperium, he said it might be local or pelvic peritonitis, or it might be diffuse, and then so severe that the rapidly fatal result left neither time to produce an exudate on the surface of the peritoneum, nor any chance for good to result from treatment, and all depending upon the virulence of the infection. The local variety, or pelvic peritonitis, was often present, the result of leakage from the Fallopian tubes, extension from an inflamed and septic endometrium, from an ovarian abscess, or of ex-

tension through the uterine wall by the lymphatics. An exudate may be formed at the sides of the uterus, circumscribed, and may terminate in suppuration, with the formation of a pelvic abscess involving the tubes and ovaries, or again, after some time, it may become absorbed. Diffuse peritonitis resulted from an extension of a pelvic peritonitis, from tears in the vagina or uterus, from a sloughing uterus or pelvic tumor, or from gonorrhœa.

The treatment was really the prophylactic one; this meant cleanliness. The treatment was considered under the following three heads: (1) To limit or do away with the source of infection; (2) to combat the systemic intoxication by supportive measures; (3) to treat such symptoms as might depreciate the patient's powers of resistance to infection, or themselves cause a fatal result. At the first signs of a peritonitis occurring, the external parts should be most carefully examined; then the uterine cervix should be carefully inspected. Then wash out the uterine cavity, thoroughly clean it, and examine with finger. He had been asked if all cases should be cleaned out, and answered "Yes, if saprophytic." He said that we might determine whether we were dealing with streptococci, staphylococci, pneumococci, or the colon bacilli, yet such information did not give us practical points for working. But if the bacteria found were shown to be streptococci, the uterus should be washed out but not curetted. Clinically and practically all that then could be done was to clean out the uterus thoroughly. Application of the ice-bag was advocated and, if this was not well borne by the patient, the application of heat. If the vagina become boggy open, break up exudate with finger, and pack the part with gauze; the limiting of the exudate will prevent the carrying of infected material into the peritoneum.

Medicinally, supporting measures, the use of large saline enemata after thoroughly emptying the bowels by a dose of calomel followed by saline laxatives, particularly Epsom salts, to prevent the exudation in the peritoneum forming a culture ground for bacteria, should be employed. The bowels are prevented from becoming paralyzed and food is more readily absorbed when such a procedure was followed. Alcohol, strychnine, and the heart tonics should be used, with easily digested nourishing food given frequently. If tympanites was marked with vomiting, lavage of the stomach was of the greatest service. Hypodermoclysis with decinormal salt solution and intravenous injections were often of great service in sustaining the patient and, perhaps, diluted the poison and caused excretion of toxins by the free action of the kidneys. The fever should be controlled by tepid sponging or the ice-bags, and not by the coal-tar products which weaken the heart if used freely. As phagocytic agents, nuclein and albuminose had been used and had certainly seemed to aid, though other agents were employed at the same time. When the uterus was septic, hysterectomy and drainage of the peritoneum had been done. When done early, the uterus might be sacrificed unnecessarily; when done late with diffuse septic peritonitis, the results were fatal; the proper time, if any, to interfere surgically was so hard to determine that, unless the peritonitis was limited when the operation was not called for, the operation was useless.

The Treatment of Gonorrhœal Peritonitis.—Dr. A. Ernest Gallant read this paper. He described the gonococcus and the manner in which it reached the peritoneal cavity. One should endeavor to check its ravages by timely education, timely eradication, and timely enucleation. He urged at length the duty of the profession in instructing the laity in regard to the dangers of infection and their serious consequences. As to eradication, he first considered children. He described the symptoms of gonorrhœa in little girls, and said that while it might involve the tubes, ovaries, and peritoneum, it never involved the uterus. The disease was occasionally, though rarely, seen in the new-born. The prognosis for little girls was good, and the disease usually terminated within three months. In the treatment of these children the vagina was irrigated with warm boric acid solution, and with the same "p" syringe one-half ounce of one-per-cent. silver nitrate solution was injected. This process was repeated every third day. A 10-per-cent. boric-acid ointment was applied twice daily to the vulva, and an alkaline diluent with copious draughts of water were administered internally. He questioned whether the disease was eradicated in these cases and whether the girl at puberty would not show the effects of her early infection. In females, after puberty, the most important indication was to arrest and limit the disease to the vagina and urethra, before the gonococcus found its way into the cervix and uterus, Fallopian tubes and peritoneal cavity. The drugs which had rendered most efficient service were silver nitrate and ichthyol. The introduction of a sound or instrument carrying a drug into the cervix was no longer practised on account of the danger of conveying the gonococci higher up and thereby infecting the uterus. He believed with Neisser that once the gonococci invaded the uterus there was little chance of medical treatment availing; one must never lose sight of the danger of stirring up the enemy and thus facilitating his entrance into the tubes and peritoneum. When the gonococci invaded the peritoneal cavity, pelvic and abdominal pain was incited. There was increased temperature and pulse. As the gonococci did not grow at a temperature lower than 79° F., or above 100.4° F., we might take advantage of this fact and make use of an apparatus suggested by Stroynowski (*Centralblatt für Gynäkologie*, December 13, 1902) for the local application of cold to the female pelvis by a continuous current of hot or cold water within the vagina. In regard to timely enucleation, in a majority of active gonorrhœal infections, uterine, tubal, or peritoneal, one hesitated to bring into play either the curette, or the vaginal or abdominal incision, until after the acute symptoms had subsided, and then only if the general health suffered or local symptoms persisted to such a degree as to disturb menstrual, marital, or maternal functions. He related a case upon which an operation was performed for appendicitis, and upon opening the abdominal cavity gonorrhœal peritonitis was found as well, as an illustration of some of the difficulties that prevented one from making hard and fast rules. He related another case which illustrated the too common course of gonorrhœa, viz.: Early infection, exacerbations, metrorrhagia, pyosalpynx, tuboovarian abscess, ovarian cyst, appendicitis, operation, post-operative neurasthenia.

Dr. S. Marx said that Dr. Grandin's paper was interesting to him and particularly his division of post-operative peritonitis into the paretic or pseudo-peritonitis, the inflammatory and the septic, and also his means of differentiating them. He did not believe the line of demarkation could be so finely drawn as depicted by the author. Some years ago he had used codeine in the treatment of peritonitis, but found that it was not as efficacious as had been claimed for it, and lately he had been using opium in enormous amounts, following out the teachings of his late teacher, Dr. Alonzo Clark. In the inflammatory conditions he attempted to paralyze the patients with opium. Regarding the septic form of peritonitis he advocated radical surgical means, opening the abdomen, washing it out, etc., and then using the antistreptococcic serum. In the puerperal cases laparotomy plus the serum did not yield good results with him. He said that something more radical should be attempted in these cases. He said that Dr. Murray's paper was a very important one from the standpoint of drawing the attention of the members to the treatment of puerperal peritonitis, *i.e.* its septic nature, and to the vast importance of an inspection of the genitals. During the past six weeks he had seen from thirty to thirty-two cases, and in not a single instance did he find it necessary to enter and wash out the uterus. There was found in each instance a local exudate in the

vagina or on the cervix, and this, when thoroughly destroyed, caused a subsidence of the symptoms. These same cases, if seen five or ten years ago, would have been curetted,.and this probably explained why, at that time, his mortality was so high. In not a single instance had he found it necessary lately to introduce the hand into the uterus. He believed that if nothing was in the uterus it was not necessary to use the curette; but if something was there it should be removed. He again emphasized the importance of a careful inspection of the genital tract. In cases of septic peritonitis following labor the results were bad, and in spite of the use of opium and drainage, etc., a large number of these patients died. He had on different occasions been tempted to do a hysterectomy, but did not, and at the post-mortem conditions were present at variance with what were supposed to be there, and he then found that such interference would not have saved the patients and was thankful for his non-interference. To operate early in puerperal peritonitis, *i.e.* hysterectomy, he believed to be a crime and to operate too late was futile. Where, then, is the happy middle ground?

Dr. Hermann J. Boldt, in speaking of the differential diagnosis between the suppurative and the puerperal form of peritonitis, said that symptomatically they were practically identical. In septic peritonitis the temperature always remained low, as a rule, although occasionally one met with exacerbations when it ran up to 105° or thereabouts, and then dropped to 100° or 99°. Usually the abdomen was flat. To illustrate the futility of attempting to make a diagnosis of any particular form of peritonitis and to tell what the real condition was, he reported a case which showed how impossible it was to be guided by any set rule, so far as symptomatology and bacteriology were concerned, and to say what form of treatment should be employed in every case.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, Held January 13, 1904.

Dr. William Hallock Park in the Chair.

Some Observations on Lymphatic Leukæmia.—Dr. L. B. Goldhorn read this paper. He said that during the past years he had had the opportunity of examining the blood of a number of cases of lymphatic leukæmia, and the last one examined had presented such remarkable departures from all the others that he reëxamined many slides and wished to present the inferences that he had drawn.

Morphology of the Blood in Leukæmia.—He said that leaving out the pseudoleukæmia infantum of von Jacksch there were two distinct forms of leukæmia which he called lymphatic leukæmia and myelogenous leukæmia, so omitting the usual addition of "spleno" or "lieno" on account of the not infrequent involvement of the spleen, in the lymphatic variety. From a hæmotological point of view, which he regarded as the only proper one, these two were readily held apart; from a pathological or anatomical point of view that seemed to be impossible. If one divided the leucocytes into two great classes, the hyaline and granular ones, he said that in the myelogenous leukæmia there was an increase in the granular varieties, and in the leukæmic one an increase in the hyaline forms with a probable exception of the mononuclears and transitionals. The myelogenous form was a new growth of the centers of the bone-marrow which gave origin to the granular leucocytes of the blood and the lymphatic form a hyperplasia of those centers which supplied the blood stream with lymphocytes. Both could form metastases like malignant new growths, the pathological changes in the viscera depending upon them. Just as no two cases of carcinoma with metastases were alike, so no two cases of leukæmia were alike. Recognizing that leukæmia was not a disease of the blood proper it was to be expected that the changes in the red blood and the plasma would vary as the nature and seat of the metastases varied. This was the way he had been able to explain to himself the enormous differences in the degree and character of the different cases of leukæmia. So far he had not had any difficulty in telling the two leukæmias apart. In myelogenous leukæmia he looked upon the mast-cells as the sole characteristic cell; their enormous increase formed so constant a feature that they appeared as pathognomonic, for while there were many diseases in which the myelocytes were increased, myelogenous leukæmia seemed to be the only one in which those cells were so abundant as to give a characteristic aspect to the blood picture. This he stated was not usually taught, and the reason seemed to have been inadequate technique in the demonstration of those cells. Before the invention of the Jenner stain the demonstration of the granules of those cells was a difficult as well as a tedious matter. For their rapid demonstration he suggested a saturated solution of a basic dye like methylene blue or Dahlia in ordinary wood-alcohol. Their granules were brilliantly stained by applying this solution to the unfixed blood smear for a few seconds and washing in water. He had been unable so far to obtain a bood smear from a case of undoubted myelogenous leukæmia in which he could not readily in this manner show this cell in enormous numbers. In what had been termed a mixed leukæmia an enormous increase in the various granule-bearing leucocytes was seen, together with what appeared to be large mononuclear hyaline cells; having Ehrlich's classification in mind, this did not seem to him a leukæmia of double, viz., myelogenous and lymphatic. origin, but one of purely myelogenous origin, in which the mononuclear cells were not lymphocytes, but the mononuclear and transitional cells of Ehrlich. A mixed leukæmia would, under these circumstances, appear to be of very rare occurrence, as rare as a carcinoma with a sarcomatous element in it.

A Case of Lymphatic Leukæmia.—The last case he examined was a lady seventy years old, a patient of Dr. Fisk, who furnished him with the following notes on the physical examination: The spleen at present reached down to the umbilicus; in the later part of October it reached only half as far. The leucocyte count then showed 100,000 less cells per cm. than now, but this was probably insignificant, as the leucocytes fluctuated enormously in some cases even during the twenty-four hours. There was no glandular enlargement otherwise, although the liver reached below the free border of the ribs. The patient suffered from diarrhœa, and when this was controlled the patient improved steadily while the splenic tumor increased. He was surprised to find no distinct evidences of anæmia. There were no blasts of any kind, no poikilocytes, no washed-out corpuscles, none of the common degenerations, no increase in blood platelets, but a leucocytosis of 500,000. Ninety-seven per cent. to 98 per cent. of these leucocytes were lymphocytes. Eosinophiles, neutrophiles, and mast-cells were just about normal numerically, *i.e.* per cm. The great majority of the lymphocytes were small lymphocytes, showing but little degeneration. The hæmoglobin was high, giving a high color-index, but it was known that its estimation was not a simple matter in leukæmia. This was about the only condition in which he could recommend the use of Talquist Filterpaper book. He believed this book to be unreliable because it gave in all cases of lessened oxidation of the blood, and markedly in cases of cyanosis, a reading which went eventually much beyond the scale of the color-comparison chart. After comparing the blood findings in this case with other cases he expressed a belief that the prognosis in this case was good, and, to his great satisfaction, Dr. Fisk told him of another case of leukæmia in which the splenic tumor reached to the symphysis pubis and in which there was otherwise no demonstrable infiltration of the lymph nodes. This case ran a very chronic course.

A marked contrast to this case was one which he saw four years ago and which came to autopsy. This patient had a marked lymphæmia and an anæmia of exceptional high degree. He had the pleasure of showing a prepara-

tion of this case to Professor Ewing because he found a number of undoubted megaloblasts besides some myelocytes. There was at the same time a distinct increase in the polynuclears, and many of these showed kariorrhex as Professor Ewing had seen in a similar case before. At the autopsy foci in various stages of breakdown and softening were found in the viscera, and the red marrow shows a picture resembling that seen in cases of pernicious anæmia. In other words, he said the blood picture reflected the condition of the viscera.

Besides these two extremes he said he had preparations from intermediate cases. In one there was before death but little of a splenic tumor, but on the other hand there was much glandular infiltration. Blood smears from this case showed numerous normoblasts; some of these showed exquisite mitoses, and the blood picture was otherwise that of a secondary anæmia of high degree. It was frequently stated that while nucleated red corpuscles were readily found in the myelogenous form they were usually rare in cases of lymphatic leukæmia. This seemed to him to be a mis-statement, the presence of the blasts going simply hand in hand with the nature and degree of the anæmia which might be present. He said it suggested to him the fact that the extent and nature of the anæmia which might be present depended upon the site and nature of the metastases, on the amount of breakdown in such foci, and the consequent absorption of metabolic products from them. At all events it appeared to him that the careful study of the red blood and leucocytes other than the usual lymphocytes was of paramount importance when it was a question of what progress the disease was making, especially also as there did not appear to be any constant relationship between the splenic tumor or the glandular enlargement and the progress of the disease.

Dr. Goldhorn then gave a black-board demonstration of his method of counting blood-cells.

Some Observations on the Thread Reaction.—Dr. E. LIBMAN said that there had been described three forms of reactions which were supposed to be specific—the agglutination reaction, the thread reaction, and the recently described amorphous agglutination reaction of Schmidt. There had not yet been sufficient work done on the thread reaction. The subject was first prominently brought forward by Pfaundler. He had investigated a number of cases of infection by the colon bacillus, and had obtained thread reactions in a number of instances by testing the serum obtained from the patient with the colon bacillus obtained from the infection in the same patient. In non-febrile cases he obtained agglutination reactions. Pfaundler had claimed that the reaction represented more than a specific reaction, viz., an individualistic one, because the serum from a given patient had no effect upon the colon bacilli from other patients, nor was the colon bacillus from a given case affected by sera from other cases. The thread reaction usually appeared after a few hours. Krauss and Loew threw doubt on the claim of Pfaundler because they had found thread reactions occurring both with organisms from a given case and from other cases.

Dr. Libman demonstrated that there were really two forms of thread reaction. In one the organisms grew as a continuous thread; this was often referred to as the "end-to-end" reaction. He has found this reaction often under such conditions that one could be sure that the reaction was not specific. The other form of reaction should properly be called the "chain reaction." In this reaction the organisms were made to grow in threads, but in the threads the organisms appeared to be distinct and looked like streptococci. This reaction when complete, Dr. Libman had found to be more specific than the agglutination reaction. He said that the tests performed in obtaining these reactions must be carefully controlled, for there were a large number of conditions under which bacilli could be made to take on a coccoid form.

Dr. Libman referred to a case in which he found the thread reaction occurring in the human body—in the gall-bladder. He said that in making the tests one must use very thin emulsions of the organism. He referred to the possibility of mistaking coccoid forms of the colon bacillus in urine for streptococci.

Dr. PARK said that in his work the dysentery bacillus he frequently came across thread reactions; in order to have thread reactions one must have growth. Simply by changing the temperature or changing the media one could make the reactions or not make them—for instance, if one used the serum at a dilution of 1 to 500 at a temperature at from 15° to 18° C. there would be no reaction, but if the temperature were raised to 24° or 30° C., there would occur a good reaction. One could make thread reactions at will by remembering that anything which prevented growth would prevent thread reactions.

Dr. Libman said that he would lay stress only on those reactions in which the organism assumed the coccoid form.

Dr. VAN HORN NORRIE asked Dr. Libman regarding the difficulties with the Gram stain for gonococci occurring in the urine.

Dr. Libman answered that if the urine was too acid the Gram positive organism might be decolorized by the Gram procedure, and if the urine was very albuminous and the specimen overheated, organisms which were usually Gram negative might hold the Gram stain.

Comparative Morphology of Vaccine Bodies.—Dr. JAMES EWING presented specimens and drawings of vaccinia of the rabbit's cornea, frog's skin and cornea, and mud-puppy's (*necturus*) skin; diphtherial necroses of the rabbit's cornea, frog's cornea and skin, and salamander's skin; and the skin of a case of measles dying in the full eruptive stage of the disease. The specimens were stained by fuchsin and indigo carmine (Borrel's method).

In describing the specimens the speaker said that in taking up the study of variola in 1901 he had chiefly in mind the hope that the application of Nocht's stain to smears from the lesions of the skin and respiratory mucous membrane might be successful in demonstrating the presence of a protozoon. The results proved negative. Likewise the results of a study of fresh material examined on a warm stage, from variola and vaccinia, were negative not only as to the presence of any recognizable protozoon but as well in regard to the question of amœboid motion of any definite structures in the tissues. The histological study of the tissues while defining a great many structures which suggested a protozoon origin had left him as it had previously left the majority of observers not only in doubt about the origin of many of the suspicious forms, but with the moral certainty that the morphological study of the vaccine body series in variola and vaccinia could hardly be relied upon to yield positive conclusions even to the most experienced observer, while the type of evidence reasonably demanded to convince others of one's conclusions regarding the nature of these bodies seemed much less likely to be obtainable from this line of study. It seemed possible, however, that the study of the changes in the epithelial cells of other classes of animals which might be made to react to vaccine could yield information of value by establishing a comparative morphology of vaccine bodies. The conflicting statements regarding the possibility of producing genuine vaccine bodies by other means than by vaccine also suggested that this subject deserved attention from the same point of view, and would especially assist in separating simple degenerative products from what might prove to be a real protozoon among the host of peculiar structures seen in variolous lesions.

With these objects in view he had compared the changes occurring in the epithelial cells in human variola with those occurring after vaccination in the rabbit, frog, mudpuppy (*necturus*), and salamander; with those resulting from the action of diphtheria toxin, after Sikowsky's method, in

the cornea and skin of the rabbit, frog and mudpuppy; and with those seen in measles.

Among the characteristics of the ordinary vaccine body might be mentioned the perinuclear position, which is not invariable, the clear zone surrounding the body which is probably an artefact but a very constant one with the larger bodies, and the variable staining reaction, some bodies being basophile, others acidophile, while many show both basophile and acidophile portions. The more recently added members of the series, including signet rings, rosettes, crescents, and "encysted" bodies must be regarded at present as of uncertain relation to the simpler bodies first described by Guarnieri.

According to his own observation, the most significant feature of the ordinary vaccine body was the fact that some are basophile, some acidophile, and others possess both basophile and acidophile portions, either compact or granular or vacuolated.

Proceeding to a brief description of the bodies observed apart from variola in man or vaccinia of the rabbit's cornea, may be mentioned first the bodies produced by vaccination of the frog's skin and cornea. Here he had more negative than successful results, and had inoculated many frogs without any definite effect on the epithelial cells. In the best results a localized lesion of the cornea, and a more diffuse lesion from extensive scarification of the skin were observed. In both locations the bodies were much more numerous than in variola, and included many small acidophile and basophile perinuclear forms, some rings, and cysts containing 10–50 homogeneous globules or vacuolated bodies or rings. In the frog's skin the specimen exhibited seemed to show rather clearly that many of the bodies had resulted from the comminution of the nucleus. Others had a different origin, which seemed explicable from the changes produced by diphtheria toxin. In the same locations in the frog diphtheria toxin in twenty-four to forty-eight hours induced cell changes and nuclear and cytoplasmic alterations which seemed to differ from those following vaccination only by their greater intensity. Mechanical influence might have been responsible for some of the changes following vaccination of the frog's skin but not in the cornea, but numerous negative results of vaccination of the frog's skin indicated that the effects of trauma were unimportant. He was inclined to believe that a true progressive vaccine process existed in the skin of the frog in the case exhibited, since this lesion was so extensive.

Comparing the lesions produced by diphtheria toxin with that of vaccine in the rabbit's cornea, there appeared many points of similarity and quite as many differences. The toxin failed, at least in forty-eight hours, to cause the swelling of the cell layer characteristic of vaccine, and the lesion was more intense and the bodies more numerous than with vaccine. Among the changes produced by diphtheria toxin were (1) keratinization of whole cells or of the whole cell layer, the nuclei staining blue after Borrel's stain; (2) keratinization of cell body alone; (3) keratinization of the perinuclear zone of cytoplasm; (4) separation in globular form of keratin masses, which, either in the same or in other cells, assume the perinuclear position and appearance of the vaccine body; (5) transformation of the cell into a cyst containing a great variety of globular, or vacuolated and ring-shaped bodies. Some of these were strikingly geometrical in form and might be described as rosettes. (6) A peculiar series of changes consisted in the formation in the nucleus of one or several large or minute acidophile rings. (7) From the nucleus was sometimes extruded a large strongly acidophile cyst-like body inclosing acidophile granules and minute rings. (8) The peripheral portion of many of the globular bodies broke up into granules, which were often regularly arranged in a fringe about a homogeneous central body which was either acidophile or basophile.

The fate of all that portion of the nucleus, except the nucleolus, was a matter of great interest. Careful study of the specimens seemed to demonstrate that the nuclear material, apart from the nucleolus, did not become incorporated in the fuchsinophile substance, but took the form of the basic-staining vaccine body.

In many nuclei, with or without nucleoli, there appeared a homogeneous basophile substance which sometimes showed convoluted edges, or many regularly placed vacuoles, or became broken up into rings. This substance stained brown or blue with Borrel's method, and black after iron-hematoxylin. Very similar vacuolated nuclear bodies were seen in measles.

Fuchsinophile intranuclear vacuolated bodies and rings were encountered in diphtherial necroses, and in some foci the changes consisted almost exclusively in the formation of intra- and perinuclear acidophile rings. In variola, especially in the trachea, the multiple nucleoli of the epithelial cells could often be seen to increase in size and develop several small or large vacuoles, and to appear as congeries of rings. In general, it might be said that while diphtheria toxin did not reproduce the corneal lesion of vaccinia it produced definitely many of the typical forms of true vaccine bodies. In the rabbit's trachea diphtheria toxin produced a great variety of spheroidal or ring-shaped, or vacuolated intracellular bodies, many of which resembled the bodies seen in the human trachea in variola. In the rabbit's bladder, diphtheria toxin produced the usual changes in the epithelial cells, and here many red blood cells had been extravasated into the epithelial layer, fragmented, and lodged between the epithelial cells or about their nuclei.

In the mudpuppy (*necturus*) the inoculation with vaccine in the skin and cornea produced a good deal of keratinization of cells. This formation of homogeneous acidophile material could be seen very definitely in the very large cells of this animal, as beginning in the cytoplasm near the nucleus and forming an isolated perinuclear mass resembling a huge vaccine body. Yet the resemblance to the vaccine bodies of the rabbit was extremely distant on account of the large size of the cells. The nucleus and body of the pigmented cell of the skin in necturus frequently became fused into a homogeneous mass and assumed a perinuclear position in other cells. Changes in the nucleoli were not observed in necturus.

Inoculation of the skin of the salamander produced much the same lesions as in the frog, but the bodies were much larger and much difficulty was experienced in distinguishing the globules derived from epithelial cells from fragments of red blood cells.

Measles.—In the skin of a case of measles dying in the full eruptive stage of the disease, the epithelial cells in numerous marked foci and diffusely, were found to contain a great variety of intracellular bodies, many of which were identical in appearance with the bodies in variola. In certain foci these bodies were much more numerous than he had ever seen in variola. They presented a greater variety of form, and the same variation between acidophile and basophile staining tendency. Keratinization of complete cells and fragmentation of these cells was frequently encountered. Indeed, the whole process seemed to be a part of the hyperkeratosia which produced the large flakes thrown off in desquamation in this disease. Among the separate bodies were some which might be described as rings, basophile crescents with acidophile nuclei, vacuolated crescents, pyramidal bodies capping cell nuclei, large basophile or acidophile bodies with vacuoles symmetrically arranged, and many other forms shown in the colored sketch. He could find no satisfactory evidence that these bodies had any other origin than from the epithelial cell bodies and nuclei. After Borrel's stain, the resemblance of these bodies to those produced by diphtheria toxin, or to those seen in variola appeared to be distinct. The acidophile forms seemed traceable to nucleoli and keratinized cell bodies, and the basic bodies, blue and brown, appeared to come from the basophile

elements of the nuclei. Nevertheless, the resemblance of many of these bodies to developmental forms of a hypothetical protozoon was admittedly great.

The occurrence of keratinized cells in the epithelial layer had been described and depicted, especially by Bosc in variola (*Centralblatt für Bakteriologie*). This observer correctly stated that whole keratinized cells were readily separated from the "infected" cells in these lesions, but he did not appear to have considered the possibility that these cells might become fragmented and the fragments englobed by healthy cells. Many of the parasitic forms appearing in his sketches were definitely reproduced in the lesions caused by diphtheria toxin.

Foà had recently reported (*Archives de Parasitologie*) that the bodies produced by diphtheria toxin did not resemble true vaccine bodies, which, however, she believed to be degenerative products. No details of this failure to verify Sikowsky's results were given, and this part of her extensive study of vaccine bodies did not appear to have been regarded as of much importance.

The conclusions drawn from this study were as follows: The inoculation of vaccine and diphtheria toxin in various animals produces a peculiar form of coagulation-necrosis, or keratin necrosis, which has been imperfectly recognized and understood, and which results in the formation of homogeneous acidophile material that may be drawn out into fibrils, or broken up into globules, or granules, vacuolated, and englobed by the more healthy epithelial cells in which it appears in the positions occupied by vaccine bodies.

This type of necrosis occurs in variola and measles, and the bodies produced by it are abundantly present in the epithelial lesions of these diseases. Some of these bodies have been included in the cycles of hypothetical protozoa described by many authors in variola.

While forms of a true protozoon may be mixed up with these degenerative products in variola and measles, he was unable to convince himself that any such theory was necessary to account for the suspicious bodies.

Some of the suspicious bodies in variola he had been unable to find fully paralleled in diphtherial necroses, especially the presence within the nuclear membrane of several distinct rings of considerable size, and he intended to repeat the systematic comparison of variolous and diphtherial lesions before concluding definitely that no protozoa can be demonstrated in variola or measles. He was strongly of the opinion, however, that the intranuclear rings were vacuolated fragments of nucleolar and nuclear material.

Demonstration of (1) "Vaccine Bodies" in Monkey's Skin (Prepared by Dr. Flournoy); (2) Smears from Vaccine Vesicles (Wright's Stain).—Dr. A. W. WILLIAMS made these demonstrations and stated that the sections of rabbits' corneas showing in the epithelial cells changes due to diphtheria toxin, as prepared by Dr. Ewing, made her even more inclined to think that most, if not all, of the changes seen in the epithelial cells in the lesions of smallpox and vaccinia were due to degeneration and necrosis of the cell contents. The two smears, one from vaccine vesicles and the other a control, from staphylococcus pustules of the rabbit's skin were brought to show that both had epithelioid cells containing similar vaccine-like bodies, and that both had a large number of granules in and between the cells. These granules were eosinophilic, basophilic, and a mixture of both, and some showed beautiful signet-ring shapes. The granules had been studied because they were able to obtain from rabbits vaccine virus filtered through the thickness of the finest filter paper an almost clear filtrate which was bacteria-free and in which only small granules were seen, but which produced an abundant typical vaccinia when rubbed on freshly-shaved rabbit's skin. She said it had been impossible so far to discover characteristic granules. Among the various stains used Wright's modification of Romanowski's stain had been chosen for the demonstration of those smears because it had been used recently so successfully by Wright for staining the intracellular protozoan causing Delhi boil. Wright's method had also been used for the stained specimen of Trypanosoma Lewisi. This trypanosome, Dr. Park thought, might be of interest because it came from one of Novy and MacNeil's test-tube cultures, the first pure cultures of a protozoan which had been obtained on artifical culture media. The specimen given to Dr. Park about two weeks ago was inoculated into the peritoneal cavity of a white rat and the rat was killed on the eleventh day following, and from the heart's blood there was made the two specimens shown, one a hanging-drop, and the other a dried film. The *trypanosoma Lewisi* was a flagellate found frequently in the blood of rats, but seldom causing the death of the animal. She said this flagellate was also of interest from the fact that it was very similar to the *trypanosoma Brucei*, the cause of the fatal *nagana*, or *tsetse-fly* disease of horses in West Africa, and the *trypanosoma evensi*, the cause of the *surra*, a similar disease met with in India. Since 1901 a number of cases of human infection by an apparently distinct species of trypanosome had been reported.

THE PITTSBURG ACADEMY OF MEDICINE.

At the meeting on March 22, 1904, the president, Dr. Ewing W. Day, being in the chair, Dr. MacFarlane reported a case of a man twenty-four years of age, who in 1898 had an enlargement of the cervical lymphatic glands. Two years later they had developed to an enormous size and were removed by the late Dr. McCann. Six months later the glands again began to enlarge, and now there was a large mass on the right side of the neck, from the auricle to the clavicle, with venous enlargement all over the mass. The question in diagnosis had been between tuberculosis, lymphsarcoma, and Hodgkins' disease. Tuberculosis was excluded. The patellar reflexes were normal; the gait was ataxic, probably due to involvement of the cord; no splenic enlargement; slight apical dulness; leucocyte count, normal. The case was deemed inoperable. A large specimen taken proved on microscopical examination to be lymphosarcoma. Dr. Anderson reported a case of a boy eleven years old, with a mass of glands extending from the ear to the clavicle. Many glands were removed and the disease was diagnosed clinically as lymphadenoma. Dr. Ingram reported the finding of a bacillus in the glandular mass removed. The boy's father had died the year before of some swelling in the neck, thought to be Hodgkins' disease. In the case of the boy the glandular enlargement had recurred in the axilla. Dr. MacFarlane said that the pathologists themselves were unable to distinguish between lymphosarcoma and Hodgkins' disease; clinically the diseases had not been distinctly separated. He thought the special point of interest in the case he reported was the ataxic symptoms which negatived operation, and the absence of respiratory disturbance. Dr. Adolph Koenig read a paper entitled "Notes on Typhoid Fever." He summarized his treatment as follows: (1) Absolute withholding of food, alcohol excepted, during the period of anorexia; (2) the ingestion of large quantities of water —2 to 4 quarts in twenty-four hours; (3) the administration of guaiacol with small quantities of whiskey every two hours; (4) administration of magnesium sulphate sufficient to provoke from one to four movements a day; (5) sponging—cold or tepid—to produce leucocytosis, lower temperature, and quiet the nervous system.

Dr. Litchfield said that during three months' service at the West Penn Hospital in 277 cases treated with acetozone he had a mortality of 9 per cent.; the preceding summer in 228 cases treated with guaiacol the mortality was 11 per cent.

Dr. Simonton reported a case of typhoid fever, Widal reaction positive one to twenty-five. A large enema brought a free bowel movement, followed by complete collapse with rapid, weak pulse, temperature 104°, and

all the symptoms of perforation and peritonitis. The patient was seen by several surgeons, all of whom thought he would not live twelve hours. Three days later he passed flatus, and gradually recovered, notwithstanding an undoubted perforation and peritonitis. Dr. Lichty said that he had never been able to follow any set plan of treatment. He said that he had observed different methods of treatment in the Philadelphia Hospital, all with about the same results. He knew of one case in which the patient had died of hemorrhage thought to be due to tubbing. In about 150 cases in private practice he had two deaths from pneumonia, and one from hemorrhage—a mortality of 2 per cent.

Dr. Koenig called attention to the difference between guaiacol and guaiacol carbonate. He said many patients could not take guaiacol in liquid form; in these cases he gave it in capsule with calcium carbonate. He thought that having in typhoid a specific infection, a specified plan of treatment could be followed, with modifications to suit the case. He relied upon the tongue and not the temperature as a guide to allowing solid food in convalescence.

Dr. W. H. Kirk read a paper on "Retrochoroidal or Intraocular Hemorrhage." He said it was a rare complication in operations about the eye, but one of the most alarming accidents which could confront an operator. He thought that in nine cases out of ten there was an atheromatous condition of all the blood-vessels of the body, and this was the cause of the complication in these cases. He reported a case of a man seventy-six years of age, with glaucomatous condition of the left eye, and senile cataract of the right eye. He operated first on the right eye, using 4 per cent. solution of cocaine as an anæsthetic—making a short flap operation, followed by a small iridectomy. An hour after the operation the patient had a profuse hemorrhage from the eye, lasting ten or fifteen minutes. Three months later the left eye was operated upon under cocaine and adrenalin. Immediately after the incision was made for the flap, the capsule ruptured, the lens escaped, and hemorrhage followed.

Dr. Heckel thought that if the fundus could be examined in cataract cases, many small hemorrhages would be seen in the cases in which post-operative hemorrhage occurred.

Dr. Weisser, a guest, reported a case of cataract with plus tension seen in Wills' Eye Hospital. Dr. Posey had advised against operation, but another surgeon operated with very favorable results.

The Curative Effect of Erysipelas upon Atrophic Rhinitis.—I. Valentine Levi declares that complete cures in cases of atrophic rhinitis are exceptional. He had under his care a patient suffering from this disease. Treatment effected but little improvement till an attack of erysipelas, after which the nasal condition was greatly ameliorated. This attack was followed by two others in quick succession, after which no traces of the atrophic rhinitis remained. But there had been over-reaction, the mucous membrane of the nose was red and congested, and there was hypertrophy of the right middle and lower turbinates. Not a vestige of the original condition remains in the nose. In relation to the effect of the erysipelas on the atrophic rhinitis, the writer suggests the following factors: (1) The pathology of the two diseases is diametrically opposite: in the one there is anæmia and atrophy, in the other hyperæmia and swelling. (2) The action of the bacterial products of erysipelas on certain other diseases, as has been demonstrated. The literature on this subject is scarce.—*The Therapeutic Gazette*, March 15, 1904.

[A specialist who recently saw the case diagnosed the condition as specific. During the existence of the atrophic rhinitis the patient had no specific treatment, and if the atrophic condition depended upon syphilis, it adds interest to the case.]

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending April 16, 1904:

	Cases.	Deaths.
Measles	1416	34
Diphtheria and croup	415	56
Scarlet fever	466	28
Smallpox	1	...
Varicella	73	...
Tuberculosis	481	210
Typhoid fever	16	6
Cerebrospinal meningitis	...	45

Intestinal Perforation in Typhoid Fever.—An elaborate paper on this subject is presented by R. H. Harte and A. P. Cooper. They trace the development of surgical treatment in this condition from the first operation of Mikulicz reported some twenty years ago. Starting from that time they have analyzed three hundred and sixty-two cases of laparotomy for typhoid perforation or for peritonitis without perforation. A tabulation of all these cases is given so that future students of the question will be saved much labor in the matter of investigation of cases. Of the entire three hundred and sixty-two cases the operative mortality was 74.03 per cent. Elaborate analyses are made of the statistical material.—*Annals of Surgery.*

Tetanus and Vaccine Virus.—John H. Huddleston summarizes his conclusions as follows: (1) The fæces of calves fed on hay may contain tetanus germs. (2) Tetanus germs do not develop in glycerinated virus. (3) If any form of vaccine virus, either dry points or tubes of glycerinated virus, is infected with tetanus, it may convey it. (4) Small amounts of the tetanus infection easily fail of demonstration both by animal and by cultural tests. (5) If tetanus germs are applied in quantity to the inoculated areas of a calf at any time during the period of vaccine production, the tetanus may be present in the vaccine virus collected. (6) Inoculation by scarification is a possible method of inducing tetanus in susceptible animals. (7) It is probable that precaution against the issue of infected vaccine virus consists less in tests of the virus than in care taken during production, and especially in the cleanliness of the methods in use in the stables and in the laboratory.—*Pediatrics*, February, 1904.

Sanitary Problems at Panama.—In an article, recently published in the *Chicago Record-Herald*, Dr. G. Frank Lydston, the author of "Panama and the Sierras," has the following to say regarding the problems of sanitation at Panama: "In Panama and Colon there are a few underground channels and cesspools, but in general the sanitary provision is *nil*. Like all Latin-Americans, the natives gave it no thought. Sewage out of sight is out of mind. To correct this is a comparatively easy engineering problem, and need not worry a department that has cleansed Havana and Manila. It is the drainage of the swamps that will tax American ingenuity and patience. I cannot believe that any system will be able to carry away four feet of rainfall every year so thoroughly that the marshes will be dry and the soil not soggy. Perhaps the necessity may be relieved somewhat by establishing camps for the workmen in the temperate latitudes of the Cordilleras, which form the backbone of the Isthmus. The Isthmus is so narrow that the distances from the camps to the scene of work would not be prohibitive. In fact, the men would not have to travel further to go to their day's work than a great many laborers go to and fro every day in America. I am convinced that any other plan to overcome climatic obstacles will cost more than all the other expenses of construction combined. Surely something must be done, or the Panama Canal will die of Chagres fever. Medical science cannot save it against the forces of nature."

SOME OBSERVATIONS ON THE SURGERY OF THE COMMON DUCT OF THE LIVER.

BY WILLIAM J. MAYO, A.M., M.D.,
ROCHESTER, MINN.
SURGEON TO ST. MARY'S HOSPITAL OF ROCHESTER, MINNESOTA.

IT is at least a fascinating theory, and while not proven it can be said to be altogether probable that the gall-bladder is infected through the bile in the large majority of cases and not by way of the common duct and duodenum. Undoubtedly this latter route of bacterial invasion takes place, especially in the more serious grades of infections and often without stones.

The early experiments, which showed the normal bile to be sterile, have proved untrue, and we must look upon the biliary secretion as containing a few bacteria which can be detected if a sufficiently large quantity be examined. In the formation of stones, the necessary attenuation of the infective agents is obtained by passage through the liver under conditions which have proved most difficult to duplicate in an artificial manner, hence the few examples of true stone formation which have followed experimentation. The result is usually a more severe and non-calculus form of infection.

A gall-bladder once infected remains infected, needing only a disturbing element to reproduce its original intensity. Given an infected gall-bladder, containing stones which cause mechanical irritation, and we have the most favorable conditions for frequent bacterial excursions into the common duct, and should this be accompanied by calculi which fail to pass the duodenal orifice, we have all the conditions favorable for the development of cholangitis, pancreatitis, and so forth.

At least 90 per cent. of all of the cases of common duct disease upon which we are called to operate, arise in this way.

The primary importance of the gall-bladder must be recognized in the etiology of these infections, and operation projected at a time when the infection and stones are still in their originating viscus.

The cystic duct and its patency is a most important element in the problem, and the question of treatment is to a large extent based upon its condition. If the cystic duct is closed mechanically, either by stone, kink or stricture, a diseased gall-bladder results, which is better out than in. The infection has confined its ravages to the organ itself, and we find a cystic gall-bladder with impacted stones, thick walls, and, above all, with an obstructed cystic duct. Such organs are functionless, and if drained and left, a possible source of future troubles, among which may be mentioned reinfection, mucous fistula or colics due to failure to drain its secretions down through the common duct, and cancer. The key-note to the diagnosis of this condition is found in the fact that the gall-bladder contains no bile. Not all cystic gall-bladders require removal, as a large stone in the pelvis of the gall-bladder may block without injury to the duct—after removal of the stone bile at once appears.

In these cases, if there is no evidence of a cholangitis, there is no need of bile drainage to the surface, and the duct can be permanently occluded by ligation. Cholecystectomy is easily performed from below upward, the cystic duct and vessels are caught with forceps, a second forceps on the gall-bladder side prevents leakage and enables division of the cystic duct and vessels. The gall-bladder can be readily separated from below upward without hemorrhage or trouble. When the dissection has progressed a short distance the forceps on the deep end of the duct and cystic vessels are removed after ligature with catgut, to which latter a light gauze drain is attached to prevent displacement. This guard against leakage should always be taken.

The above method of removal enables careful ligation of the deep parts and bloodless separation from the liver, whereas, if the gall-bladder is removed from above downward the same vessels are cut over and over again, obscuring the deep field with blood.

If the gall-bladder contains bile we have an entirely different condition to deal with. Free communication through an open cystic duct means a possible infection of the common duct, and if the infection is at all marked, provision must be made for bile drainage to the surface. This can be accomplished best by cholecystostomy and draining through natural channels. Should it be deemed wise to remove the gall-bladder in such cases, we have practised in many instances amputation of the fundus, retaining the base to form a pocket from which the mucous membrane is removed, and into which the drainage tube can be securely fastened to the cut end of the cystic duct. This gives temporary bile drainage with the permanent benefits of a cholecystectomy.

The foregoing procedure is also very useful in some cases of cholecystectomy in which deep adhesions render the typical operation fraught with peril to the liver, duodenum, and deep vessels. There have been some purely theoretical objections advanced to this device and it is not ideal; but the fact remains that in a very large number of cases, it has proved both safe and curative.

Many most excellent surgeons believe that the gall-bladder should be removed in every case. In simple cases of stones with latent infections and the gall-bladder in good condition, no harm results from ligation of the cystic duct, even if patent, which is shown by the presence of bile; but in such cases, cholecystostomy gives permanent results which fully equal cholecystectomy, and has the advantage of less manipulation. It also leaves the gall-bladder which, while a vestigial remnant and probably of no value, we are by no means sure should be sacrificed unnecessarily. Time, however, may prove the radical course the proper one to pursue in all cases. Certainly in our experience, cholecystectomy has had a rapidly growing field of usefulness.

We hear much about hepaticus drainage—that is, the opening of the common duct and introduction of a tube drain into the hepatic duct; but we must

not forget that the cystic duct is an offshoot of the common duct and, if patent, furnishes natural drainage to the surface. In many cases, however, direct tube drainage from the main ducts is life-saving. Bile drainage through an open cystic duct amounts to identically the same thing, differing only in degree, and the question to be decided is as to when it will not be sufficient. We have usually found it efficient, and unless the common duct has been opened for the removal of stones, natural drainage by way of the cystic duct and gall-bladder furnishes results which, when compared with indescriminate opening and tubage of the common and hepatic ducts, proves the former method both safe and easy, and greatly lessens the disability.

In a few cases the cystic duct has not been sufficient for this purpose. We have then removed the gall-bladder and split the cystic duct down into the common duct and drained the deep ducts.

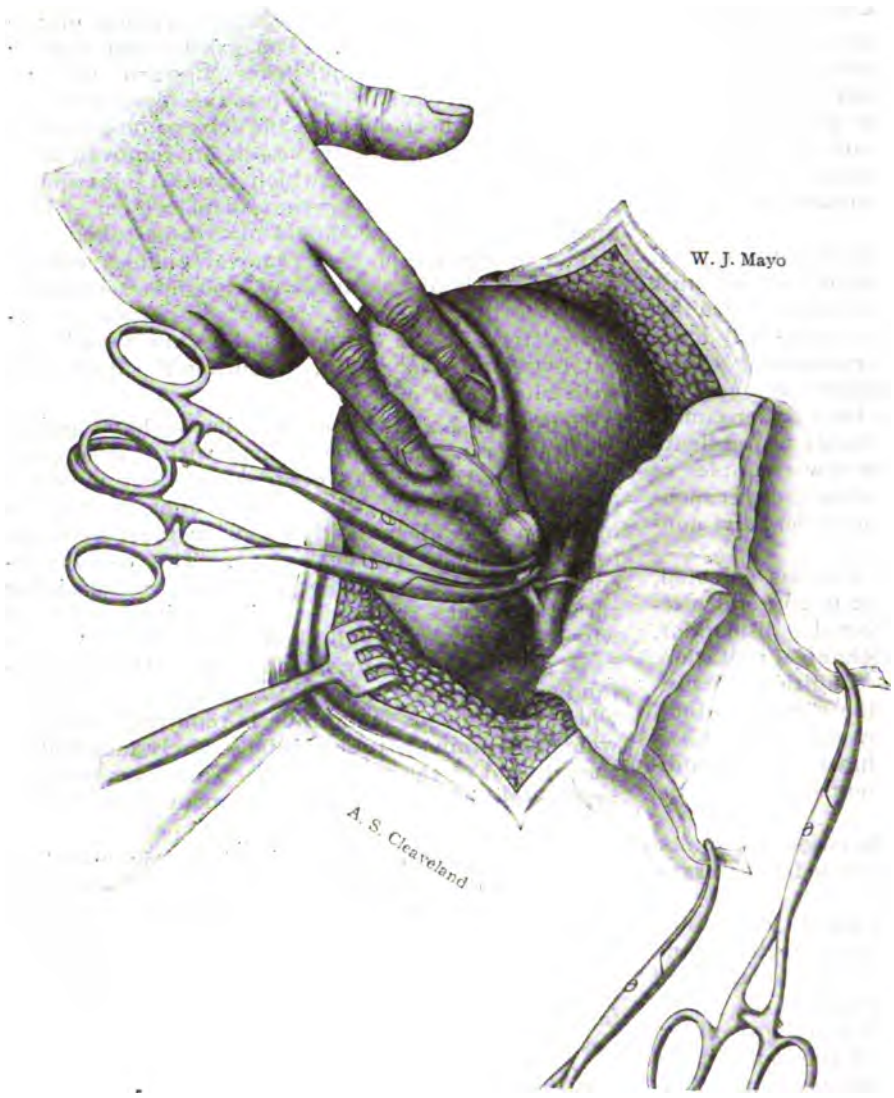

FIG. 1. Cholecystectomy, showing clamps applied to cystic duct and cystic vessels.

Stones in the common and hepatic ducts require removal and drainage. In a considerable number of cases, stones in the deep ducts may be latent, giving no symptoms and especially without jaundice. Therefore, it behooves us to examine carefully the ducts for stones in all cases, even if we have no special reasons to anticipate their presence beyond the fact that the gall-bladder contains calculi.

For all operations on the ducts, Robson's technique should be employed, the sand-bag under the back, longitudinal incision of the right rectus muscle, with division of its inner half at the curved margin of the costal arch up to the ensiform cartilage (Bevan). In two of our cases, at the extreme upper limit of this incision, the anterior mediastinum has been opened, allowing air to suck back and forth. This is rather startling, and makes one think the pleura has been accidentally injured. A few catgut sutures close the rent and no harm results.

If the common duct contains stones, one is seized between the left forefinger and thumb, and, using the stone as a guide (Elliot), two lateral mattress sutures are placed, leaving a free space between for longitudinal incision of the duct in its visible portion between the cystic duct entrance and the duodenum. These two threads with long ends act as tractors, and after removal of stones may be crossed to unite the duct margins, always leaving a little chance for drainage at the ends of the incision. In the majority of cases, unless the cystic duct is freely open for drainage through a cholecystostomy, it is better practice to leave the incision open, either completely or in part, and use the threads to fasten the drains in position. Fixing the drains prevents floating by biliary escape or derangement by diaphragmatic action exerted upon the liver. The gauze is surrounded on its inner and lower surface by rubber tissue to prevent peritoneal adhesions.

In septic cases a rubber tube ½ to ⅓ inches in diameter is cut fish-tailed and introduced into the dilated duct, and with a needle the tube is secured in position by the original catgut thread on each side. The outer end of the tube can be placed in a flattened flask, which is held in the dressing. A light gauze pack is placed about the tube and fastened with the same thread. The notch cut in each side of the deep end of the tube permits bile to pass on and out through the papilla at any time, and yet furnishes just as complete drainage.

In removing stones from the common duct the finger is the only reliable guide, and without it one cannot be sure that no calculi have been missed. The bile pressure will cause an *obstructed* common duct to distend to a size sufficient to admit a medium forefinger of the left hand. Stones cannot be definately located by probes or scoops, they may be but not with certainty. I have time and again removed stones until the duct appeared to be free, then with scoop and probe failed to locate more, after this Dr. C. H. Mayo has tried and failed, and lastly my first assistant, whose delicacy of touch is unexcelled. After all were convinced that the duct was free, the finger located further calculi with ease. If we have the duct open we should get all the stones. We still occasionally miss stones in the common duct because the symptoms were not sufficient to warrant incising it and palpation proved inefficient; but in all cases in which the duct is dilated and jaundice is present, if no adequate cause for the condition can be detected, we should open and explore. I would not be understood as saying that it is always possible

to put the finger into the common duct. It presupposes a dilated duct from obstruction.

As to danger of hemorrhage from the portal vein and hepatic artery in a well-conducted operation for common-duct stones, these structures are never seen. The cystic artery frequently comes off from the superior pancreato-duodenal (Brewer), and if cut, bleeds sharply and a large vein may cross the duct, and if wounded, will cause the field to fill with blood, leading to erroneous belief as to origin. These vessels are easily caught and tied.

It sometimes happens that no stone can be felt, yet from the symptoms we are morally certain they are in the common duct, while the parts are adherent, with the anatomy so disturbed that nothing, not even the duct itself can be recognized. To find and open the common duct in such cases, split the gall-bladder from top to bottom and extend the incision the entire length of the cystic duct, and from this point into the common duct. The adhesions are left intact to act as barriers to infection. After completing the common-duct work, the cystic duct is cut across near the common duct and the gall-bladder removed from below upward. Or in some cases the mucous membrane is detached as previously described. Such cases are in this way quickly and safely disposed of.

In this connection it may be well to speak of chronic pancreatitis. We have had twenty-six cases. In some of these calculi were present in the duct; but in most of them no stones were found, and either cholecystostomy or cholecystenterostomy was performed. All recovered. Four of these cases have already returned to us with renewal of previous symptoms. In each instance no stones were detected by palpation at the first operation, and in only one at the second, seven months to a year after the first, yet upon opening the common duct and exploring with the finger, a small stone was found in the ampulla in each case. The head of the pancreas at the second operation was much reduced from its former size. In two cases since that time, of apparently typical chronic pancreatitis, a small stone has been removed from the diverticulum of Vater, and in none of these cases could the stone be discovered by palpation, probing through the incised duct, and so forth. It amounts to this, that before one can be sure that chronic pancreatitis and nothing else causes the common-duct obstruction, one must open the common duct and explore with the finger. I do not wish to intimate that this is true of all cases of common-duct obstruction from interstitial pancreatitis, as we have had a number of typical examples shown by enlargement of the head of the organ, jaundice, and so forth, in whom the future history pointed to perfect recovery over an extended period. The greatly enlarged head of the pancreas, with its hard nodules in the above cases, prevented anything approaching accurate palpation of the ampulla in which the stones were contained.

It was interesting to note that in the two cases of cholecystduodenostomy the fistula had completely closed in six months to a year. The movable stone permitted escape of bile at intervals, by the duodenal end, and nature promptly closed the unnecessary opening. On the contrary, experience in a number of cases in which the obstruction has been permanent, showed a patulous opening after years had elapsed.

In operating on the common duct, we have frequently found the small flattened and dark-colored (disk-shaped) stones originating in the hepatic ducts; but invariably there has been a larger stone at the papilla. Thus showing that with an obstruction to free drainage sufficient to cause dilatation of the ducts and in the presence of infected bile, conditions are developed favorable to the formation of duct stones, but always secondary to an original blocking stone derived from the gall-bladder. It is possible that duct stones may arise primarily, but the writer has not personally observed a case.

The reparative power of the common duct is not exceeded by any mucous lined channel in the human body. One not infrequently encounters cases in which this channel after operation looks very badly with widely separated and ragged walls, and one fears that union will not take place, yet healing almost invariably occurs, whether the duct is sutured or not. During 1904 the following three cases, illustrating the reparative power of the common duct, occurred in St. Mary's Hospital. The first, a female patient, age twenty-two, with acute infectious cholecystitis and cholangitis, with stones in gall-bladder. In emptying the gall-bladder much putty-like material was forced into the deep ducts. To enable removal of this substance and proper drainage, it was necessary to split the hepatic and common ducts from the liver to the shelter of the duodenum, the gall-bladder was also removed. The margins of the common duct were approximated in three places by catgut sutures, the balance being left open for drainage. Patient left the hospital in twenty days with a healed wound, no bile was discharged after fourteen days.

The second patient was a female of thirty-four years.

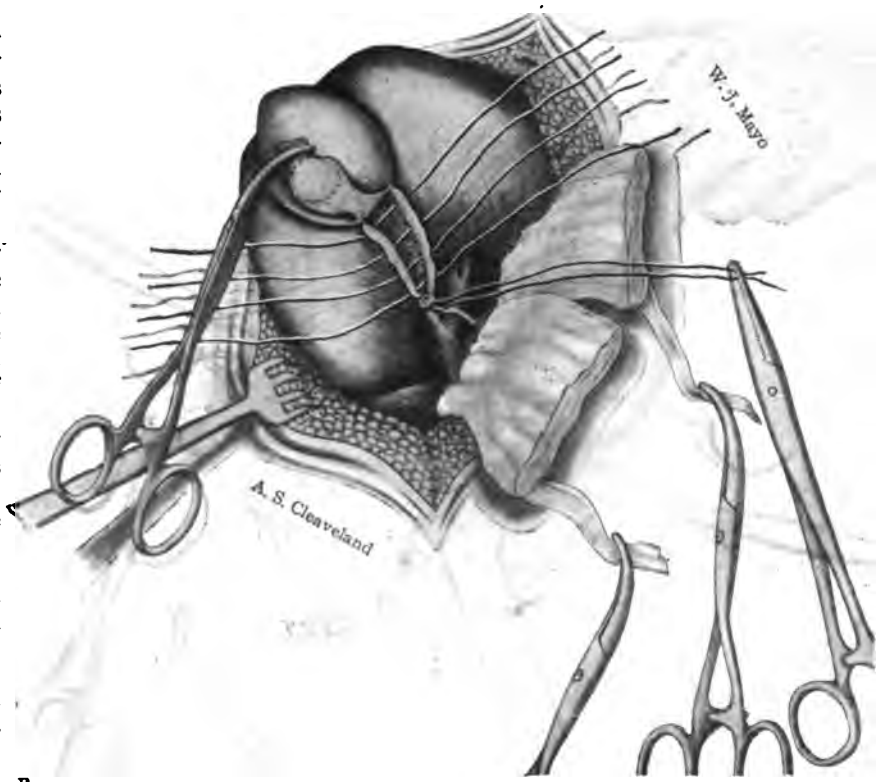

FIG. 2. Cholecystectomy, showing cystic duct and vessels ligated. Gall-bladder partially separated and sutures in position to cover the exposed liver substance.

In removing a gall-bladder which was very adherent the common duct was completely severed and the ends separated to such an extent that it was difficult to locate the distal fragment. The proximal end was made manifest by escape of bile. The severed duct was sutured end to end in three-fourths of its circumference with interrupted fine catgut sutures, through all the coats but avoiding the mucous membrane, excepting at its margin. The sheath was treated in a similar manner. It was not possible to introduce more than five to six sutures in all. One-fourth of the severed duct was left open to avoid tension and secure free drainage. Bile ceased escaping from the wound on the sixteenth day, patient left the hospital on the twenty-second day.

The third case was most interesting. A female, fifty years of age, with stones in gall-bladder and common duct. Gall-bladder malignant, involving

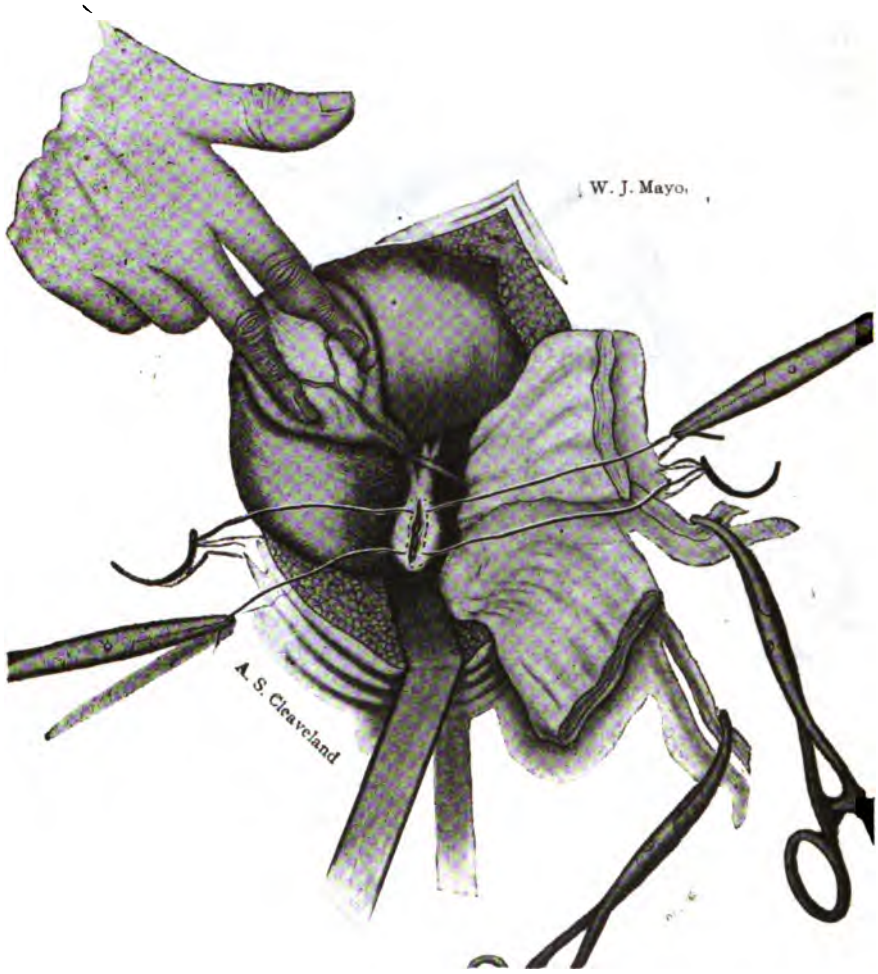

FIG. 3. Chol edochotomy, showing method of placing working sutures in common duct.

cystic duct and extending laterally upon common duct. Gall-bladder, cystic duct, and one inch of common duct excised. The duodenum and head of pancreas were liberated by incising the peritoneum and loosening the cellular attachments. This enabled the distal end of common duct, which barely projected beyond the duodenal shelter, to be brought to the short end of the hepatic duct. The duodenum was secured in this situation by sutures posteriorly. The common duct, which was dilated to the size of a lead pencil, was sutured as in the case just described. One-fourth was left open for drainage. This patient was discharged in nineteen days with a healed wound. She remained well for seven months, but now has return of the malignant disease shown by nodular tumors of the liver.

In two additional cases the common duct was excised for malignant disease. In the first the proximal end of the duct was united to the duodenum by a new opening. The third, a malignant tumor of the common duct, was excised with end-to-end suture. Death followed from shock.

In removing stones impacted in the duodenal end of the common duct, great difficulty may be encountered, and in three of our cases it became necessary to open the duodenum (McBurney), for the purpose of extracting the stone. It was only by means of this double operation that the duct could be properly cleared. The duodenum was sutured and the common duct drained in the usual manner. In a fourth case the duodenum was opened for the removal of a cancer of the ampulla and papilla. All of these cases recovered. I cannot too strongly urge the complete removal of all stones at one sitting, if the patient can bear the operation, and in our experience it has been safer than half-way measures, followed by unavailing irrigations, probing, etc., and in the large majority of cases a secondary operation of greater magnitude than the first.

Cholecystenterostomy, while not an operation upon the common duct, is indicated by disease of this channel and may be classed with it. We have only resorted to it for benign but inoperable obstruction and malignant disease. The bowel selected should be the duodenum, but in five cases this was impossible, and the anastomosis was made to the transverse colon with the Murphy button. Theoretically, this seems a dangerous practice, but in every case the result was just as satisfactory as when the duodenum was used. There were no late infections of the bile tract from colonic bacteria, and one patient lived six years, dying from a independent disease. A second is alive and well at the present time, four years later.

It is usually possible to attach to the duodenum, but until further experience has shown that it is harmful we will, in the few cases necessary, use the transverse colon rather than the stomach (Kehr) or a loop of jejunum (Mikulicz) for the purpose, especially in malignant disease.

Appended will be found a table of 107 operations upon the common duct which occurred in 728 operations upon the gall-bladder and bile passages which have been operated upon by Dr. Charles H. Mayo and myself.

BENIGN.	Total.	Recovered.	Deaths

Compound Fracture.—Reduce and dress by pouring Balsam of Peru and covering with gauze saturated with it. The fracture is then reduced, and immobilized in plaster cast for three weeks.—VAN STOCKUM, in *Presse Médicale*.

APPENDICITIS IN CHILDREN.*

By JOHN W. BRANNAN, M.D.,
NEW YORK.

The subject I have selected for this paper was chosen chiefly for the purpose of narrating the history of a case illustrating the insidious character of appendicitis in children, in the hope that others may profit by my experience, if not by my example. Appendicitis in adults has often been considered in this society, but so far as I know its special features as seen in children have not been presented as a topic for discussion.

The case I have to relate is that of a boy six years of age, to whom I was called in the evening of November 16, 1903. The nurse stated that he had complained of pain in the stomach after his supper, and had vomited a mass of curdled milk as large as an egg. With the exception of a tendency to constipation, there was nothing of importance in the previous history. On examination I found no tenderness in any part of the abdomen, though the boy complained of a little epigastric pain. The pulse was 80 and temperature 98.5°. I ordered milk and lime water, āā 3i every half hour, to be given to the patient while awake or until the vomiting ceased. In the morning of the 17th I was informed that there had been no vomiting after 3 P.M., but that the boy had been rather restless during the night. The pulse was, however, 120, and the temperature had risen to 100.5°. During the day the bowels moved slightly, and in the evening the pulse was again 120 with a temperature of 100.7°. There was no localized pain or tenderness and the abdomen was flat and soft. Calomel, in divided doses, was ordered, followed by a laxative. The patient had four movements during the night and was restless until 3 A.M. of the 18th. Then slept quietly until 7 o'clock. There had now been no vomiting for over forty-eight hours, but the pulse was 126 and the temperature 100.6°. During the day there was gradually increasing pain with tenderness, entirely confined to the *left* side of the abdomen, and in the evening the temperature was 101.2°, with pulse of 126. The patient was delirious throughout the following night, and in the morning of the 19th there was marked rigidity of the abdomen with general tenderness most marked in the left iliac region. At no time was there any special pain or tenderness in the region of the appendix. Dr. L. Emmett Holt and Dr. Andrew J. McCosh were now called in consultation and it was agreed that peritonitis was present, probably due to appendicitis, in spite of the unusual localization of the symptoms. During the day the boy twice vomited a small quantity of very dark fluid. Laparotomy was performed in the evening and a general peritonitis was found, and after some search a ruptured suppurating appendix was discovered lying deep in the pelvis near the median line. The appendix was ligated and removed, the neighboring parts cleansed and a drainage tube inserted, but the general peritoneal cavity was not washed out, as the condition of the patient did not warrant any procedures not absolutely called for. The boy recovered fairly well from the operation, the temperature falling to normal and the pulse to 110. A few hours later, however, the vomiting returned, the vomitus consisting of the same dark liquid that had been observed before the operation. On analysis this fluid proved to be composed principally of decomposed blood. The patient was fed with nutritive enemata, and for several days held his own and even improved, so that at one time it was thought that he might recover. The pulse was of good quality, varying from 100 to 110 per minute. The temperature was but little above the normal, and considerable gas with a little fecal matter was expelled from the bowel. The vomiting continued, however, at intervals of two or three hours, in spite of daily washing of the stomach, and on the fourth day after the operation the patient complained of pain in the region of the umbilicus, which gradually grew in intensity. The abdomen became distended and all the signs pointed to some obstruction of the bowels. On the 26th a secondary operation was decided upon as the only chance of saving the patient.

On opening the abdomen the omentum was seen wrapped around a coil of the small intestine in the region above the umbilicus, and low down on the left side of the abdominal cavity was a collection of pus. After free irrigation, drainage tubes were inserted into both abscess cavities, the patient being at the same time transfused with hot saline solution and stimulated in the usual manner. He, however, did not rally from the operation and died early on the following morning.

The unfortunate issue in this case made a profound impression upon me, it being my first case of the kind in so young a patient, and I have been at some pains to learn the experience of others and to consult the literature of the subject. In talking with other physicians I have found a number, even of large general practice, who have not met with a single case in young children in which an operation was called for. Other practitioners, particularly surgeons, report that such cases are not uncommon, though by no means so frequent as in adults. In a service of several years in the First Medical Division of Bellevue Hospital, I do not now recall any cases requiring surgical treatment. It is possible that patients with symptoms suggesting appendicitis are at once admitted to the surgical wards in Bellevue, for on searching the records of the Third Surgical Division for the last five years nine cases of appendicitis were found, all of which underwent operation. Apparently the admitting staff of the hospital regard appendicitis as a surgical disease, as it is claimed to be by the surgeons.

The literature of the subject is rather scanty. In a search of the journals of the last fifteen years I found but twenty-five cases, recorded by ten different observers, and in several of these the diagnosis must be considered as doubtful, the cases not having come to operation. It would seem, therefore, that appendicitis in children is not regarded as calling for especial report, for there must be many surgeons in this country who have had more than twenty-five cases in their own individual experience. Of the nine Bellevue Hospital cases referred to above four were operated upon by one surgeon, a member of this society. I have found but four published papers on the general subject, one by Deaver of Philadelphia, written in 1893, one by Manley of New York, in 1901, one by Churchill of Chicago, written last year, the fourth by Riva-Rocci, also written last year. Deaver, as might be expected from his attitude on appendicitis in adults, advocates the removal of the appendix in acute primary attacks as soon as the disease is recognized, unless there has been a decided response to judicious medical treatment, and between attacks in all recurrent cases. Churchill, on the other hand, appears to represent the conservative medical view of the management of appendicitis. Of the six personally observed cases included in his report all but two were conducted to a successful issue without operation. One of the two cases in which laparotomy was performed recovered, the other died of cerebral meningitis two days after the operation, cultures from the brain showing the presence of the colon bacillus and the pneumococcus.

*Read at the Practitioners' Society, March 4, 1904.

The youngest cases reported are one of sixteen months, by Hauck of St. Louis, and one of twenty-two months by J. E. Summers, Jr. In the second case the symptoms were thought to be due to intestinal obstruction. In both a suppurating appendix was found and removed, with ultimate recovery of the patient. In an interesting case reported by Royal Whitman, spontaneous evacuation of an appendical abscess into the rectum took place on the seventh day of the attack, following an enema given by the mother during the absence of the attending physician. As the symptoms persisted, laparotomy was performed, and the child was up and about the house on the fifth day after the operation.

F. Martin reports four cases, in two of which he opened and drained the abscess through the rectum, a tumor having been felt by the examining finger. Recovery ensued in both. One case was at first diagnosticated as empyema, later as hepatic abscess. Pus obtained by hypodermic needle passed through the seventh intercostal space in the right nipple line; a drainage tube was then inserted through one of the lower intercostal spaces behind, but with negative result. The patient died in the seventh week of illness, and on autopsy the appendix was found obliterated and the neighboring parts of bowel gangrenous. An old track of pus could be traced up behind the colon, behind and up over the right lobe of the liver to a depression the size of a hen's egg upon its upper surface. Half a gallon of pus was found free in the abdominal cavity.

In a case seen by Allingham two days after a fall out of a "go-cart," the diagnosis of intussusception or volvulus was made. The symptoms (pain in stomach and nausea) came on soon after the accident. The patient had vomited five times, and lay on the back with legs drawn up, face flushed, expression anxious, tongue dry and red, pulse rapid and hard, the abdomen generally swollen, with some soreness in median line, extremely tender to touch and slightly tympanitic. The temperature was 103°. The abdomen was opened in the median line, but nothing wrong was found until in the region of the cæcum a hardness was felt, which proved to be the cæcum covered with lymph. The appendix was distended and burst and discharged an ounce of fetid pus. The appendix was removed, the abdomen sponged out and closed with silkworm gut sutures. Recovery was complete in fourteen days. A fecal concretion the size of a cherry stone was found in the appendix.

The remaining cases do not present sufficient points of interest to repay detailed analysis. The low mortality is noteworthy. Of twenty cases in which the termination is given, only five died, or 25 per cent., whereas in one hundred and twelve cases collected by Holt, there were fifty deaths, a mortality of 45 per cent.

A few words as to diagnosis and treatment. When we have the classical symptoms of sudden and severe pain in the right iliac fossa with localized tenderness and vomiting, there is not much doubt with what we have to deal. But all writers agree that these symptoms, with the exception of vomiting, are much less constant in children than in adults, especially the localization of the pain and tenderness at the site of the appendix. According to Deaver, the pain is referred to this region in 54 per cent. of all cases, as the attack progresses, though in the beginning it is usually placed in the umbilical or epigastric regions. The location of the tenderness is much more to be depended upon, being an objective rather than a subjective symptom. In the great majority of cases the patient will wince upon pressure at or near McBurney's point. As stated by Churchill, more importance is to be attached to what children *look* than to what they *say*. In six of the Bellevue cases in which the history was obtained, there was tenderness in the right iliac fossa in all, whereas pain was referred to that region in only three. When a tumor is present or a resisting mass is felt, or there is rigidity of the right rectus muscle with flexure of the right thigh, there can be no further room for doubt.

When the diagnosis is once made, the treatment in my opinion, becomes surgical. This does not mean that laparotomy should be at once performed, but that a competent surgeon should be called in to watch the case and determine whether or not and when to operate. I have never seen a case in which operation was performed too early, but I can recall several, though my experience has not been large, in which it was resorted to too late. While the diagnosis is still in doubt or when the case first comes under observation, there is general agreement as to the course to pursue, except as concerns the administration of laxatives and of opium. Holt and Rotch both oppose the use of cathartics but endeavor to keep the colon empty by the daily use of large enemata. Deaver, on the other hand, advocates the early administration of small and repeated doses of salines, or of calomel if the stomach is not tolerant of salines. He believes that free evacuation of the bowels serves the purpose of clearing the alimentary canal of all foreign and irritating substances, relieves the congested blood-vessels, thus modifying the degree of the subsequent inflammation, and fulfils an important indication in having the bowels in the most favorable condition for operation in the event of its necessity. As regards the use of opium, the medical man and the surgeon are again opposed. Holt and Rotch agree in giving morphine in sufficient quantities to relieve pain. Deaver regards the use of morphine as bad practice because it tends to obscure the symptoms and to produce a paretic condition of the bowel, thus favoring distention. He prefers the employment of hot fomentations externally, with perhaps the internal administration of spirits of chloroform, carminatives, or extract of belladonna. I fancy that surgeons generally will agree with Deaver. They are usually called to see appendicitis after a medical man has seen it, and, after satisfying himself of the diagnosis, has given a hypodermic of morphine, and thus changed the picture in perhaps its most important feature. Probably most of us employ both laxatives and opium, according to the case. There are times when pain must be relieved and only opium will do it. In other cases, especially those seen early, a saline or calomel, in divided doses, produces the best results.

11 West Twelfth Street.

The Treatment of Chronic Middle-ear Deafness by Ozone.—George Stoker in this paper refers to that affection known as "chronic dry catarrh of the middle ear." It is generally believed to be due to stenosis of the Eustachian tube. The effect of oxygen, and more particularly of its allopathic form, ozone, in restoring a healthy condition to diseased nasal mucous membrane, and in purifying the secretions, suggested a trial of the latter in chronic progressive deafness. The ozone is generated by means of an electric current acting on a Ruhmkorff coil, to which the ozonizing tube is attached. The ozone is passed in a gentle current through a Eustachian catheter into the middle ear for about four minutes at a time, the op ration being repeated several times a week, daily, if possible. The writer then gives notes of cases. In some instances the progress has been remarkable. One favorable effect of this treatment is the disappearance of the distressing tinnitus that nearly always exists. The two results achieved by the use of ozone are—the improvement of the hearing, and the prevention of the progression of the deafness.—*Medical Press and Circular*, March 16, 1904.

URIC ACID AND ITS RELATION TO THE CLINICAL MANIFESTATIONS OF GOUT AND LITHÆMIA.*

By EGBERT LE FEVRE, M.D.,
NEW YORK.

To discuss the relation of uric acid to the clinical manifestations of gout and lithæmia is a more embarrassing task than appears on the surface, as our knowledge of uric acid is far from definite.

Uric acid as a cause of disease has been given by some writers such an exalted position in human symptomatology and pathology, that they would lead us to believe that "it really dominates the function, nutrition, and structure of the human body to an extent which has never yet been dreamed of in our philosophy, and in place of affecting the structure of a few comparatively insignificant fibrous tissues in which it is found after death, it may really direct the development, life history, and final decay and dissolution of every tissue, from the most important nerve centers and the most active glands, to the matrix of the nails and the structure of the skin and hair." (Haig.)

If one reads this same author's list of uric-acid diseases, including gout and rheumatism; the inflammatory cardiac diseases; the local inflammations of all the fibrous structures from the brain and meninges to the covering of the teeth; the functional and organic diseases of every organ and structure in the body from itch to epilepsy and pneumonia, one has an epitome of all the ills flesh is heir to. As an excepted cause of disease it is especially in evidence at the present time. It is so closely related to that aristocratic malady, gout, that those who cannot show its crest are satisfied with claiming acquaintance with its near relative, uric acid, and many symptoms that would otherwise be considered distressing are endured cheerfully. We all know with what willingness patients settle the diagnosis for us when we begin to question them by saying that they have "uric acid." Its popularity among the medical profession as an all-sufficient diagnosis is shown by the profusion with which journals devoted to uric acid and samples of medicine guarantee to eradicate it are showered upon us.

It is the limbo to which all obscure symptoms and indefinite maladies are relegated if the patient confesses to have had an ancestor—no matter how remote—who once had a pain in his big toe. As a comprehensive diagnosis it has supplanted chronic malaria, autointoxication, biliousness, and a host of others.

I do not mean to convey the impression that uric acid is not a potent cause of disease, but I do wish to emphasize that much harm is done by accepting it as the primary cause of all obscure symptoms and treating the case as if our sole object was to increase the elimination of uric acid from the body or decrease the amount found in the urine.

I also desire to call attention to the fact that precipitation of uric acid from the urine and even its accumulation in the urinary tract as calculi or gravel is not a sign of excessive uric-acid production.

Two groups of symptoms are attributed to uric acid.

First: That due to the precipitation of uric acid in the body, as occurs in acute gout with its classical localization in the big toe and other of the small joints, or in the chronic deformities of massive uratic deposits about the joints and the production of calculi in the kidneys and bladder.

Second: The other includes that large group of symptoms that are usually described as "lithæmia." The symptoms of lithæmia may be identical with those which for some days or weeks precede or follow a typical attack of gout, but which in the patients who are simply lithæmic show no connection with any gouty stigmata but which are inferred to be gouty, from their otherwise obscure nature, or from the fact that there is a more or less gouty family history.

Much confusion has resulted from the use of the word "lithæmia," as its derivation links it so closely with uric acid. Most writers have employed it as synonymous with gouty diathesis, latent gout, aberrant gout, etc., and still further fixed in minds of both physicians and laymen that all the symptoms and conditions described under lithæmia are due to an excess of uric acid in the body.

In this paper, for want of a better term and for the purpose of discussing its relation to uric acid, the word will be used in the sense that the symptoms described as lithæmic are not due to an absolutely gouty condition, although in some cases they may be associated with true gout. Gout of the gouty state (whether as articular gout, chronic gout, aberrant gout, etc.) is limited to those cases in which there are or have been deposits of uric acid in the tissues.

Lithæmia may manifest itself by merely functional disturbance or by organic and progressive lesions affecting the various structures of the body.

In some cases the condition is disturbed digestion, loss of appetite, bitter taste in the mouth, acid eructation and heartburn, bowels costive with pasty colored stools, flatulency, hemorrhoids, some dingyness of conjunctivæ and sallowness of skin. Associated with these may be mental and physical lethargy, drowsiness after meals and depression of the spirits. This condition has also been ascribed to "torpor of the liver."

In other cases the disturbance affects more particularly the nervous system. There is recurrent headache and at times symptoms of chronic meningeal irritation; neuralgias, which may involve one nerve or plexus; or may be more widespread; sensory disturbance of the abdominal viscera; cramps in the muscles, especially in the calves of the legs; vertigo, melancholia, or nervous irritability. These nerve disturbances may appear as storms and be associated with intense vomiting, diarrhœa, etc., or in the truly gouty be followed by an acute attack of gout after which the patient returns to a normal condition.

Again: the chief manifestation may be in the skin, nails, hair, or mucous membrane.

The skin in the young and well-nourished is thick, glistening, and oily. In later stages, with impaired nutrition, dry, wrinkled, and parchment-like. The skin diseases that are most common in the gouty are eczema, acne, psoriasis, urticaria, and erythema, with characteristic attacks of intense itching and congestion associated with other gouty manifestations.

The nails have fine longitudinal marking, showing their origin from the agglutination of hairs. Each gouty attack may record itself on the nails by a transverse groove.

The hair may become grayer during an attack and with the disappearance of the gouty state regain much of its normal color. The mucous membranes are frequently affected. Children with marked heredity suffer from frequent catarrhal affections of the upper respiratory passages. In adults there is frequently a chronic pharyngitis, with copious secretion and annoying cough. Spasmodic bronchitis may alternate with a true arthritic

*Read before the Medical Society of the County of New York, March 28, 1904.

attack. Acute cystitis often occurs in women and non-specific urethritis in both sexes.

The urine will vary according as the condition is acute or chronic. During the acute stage the urine is high colored and scanty, and on standing shows a deposit of abundant sediment of urates. The condition of the urine at this stage is not peculiar, but is characteristic of febrile urine. In the more chronic stages, when the kidneys have undergone organic change, the urine becomes lighter and the amount of uric acid or urates is diminished as a rule, being increased only at times when they occur as showers. The deposit of urates does not indicate an excessive secretion of uric acid, but may occur when the percentage of uric acid is below the normal, its precipitation being caused by some change in the physical condition of the urine which allows of their more rapid separation.

The symptoms referable to the circulatory system are (1) function disturbances; (2) high blood-pressure; (3) on account of the high blood-pressure changes in the blood-vessels and heart and subsequent changes in other organs.

(1) Palpitation, irregularity with a peculiar faltering, a condition described as "runaway heart," in which there are attacks of excessive rapidity, during which patients fear they are about to faint and then suddenly, with a peculiar jerk in the cardiac region, the heart resumes its normal frequency or may be even slower than normal. In other cases the disturbance takes the form of false angina pectoris.

(2) The most constant cardiovascular condition of both the lithæmic state and the true gouty condition is high blood-pressure. In lithæmia at first the high pressure may be short and coincide with the gastrointestinal or nervous symptoms, but later on it becomes permanent and is associated with cardiac hypertrophy and increased rigidity of the vessel walls, a condition giving the definite pathological entity known as arteriosclerosis.

(3) When this stage is reached the subsequent course of the patient, both from a pathological and clinical view, varies according to the organs principally affected or the functions most disturbed, so that it is possible to recognize definite types.

In the cardiac type the hypertrophy keeps pace, for a time, with progressive changes in the blood-vessels and the patient feels in perfect health except for some slight disturbance after overeating. Sooner or later he becomes conscious of an indefinite sensation of distress in the cardiac region after unusual exertion, extreme excitement, and especially on going up stairs and walking to business immediately after eating. Later he has transient attacks of faintness without cause. Examination of the heart may show either a powerfully acting heart, which seems more than sufficient until its power has been tested by the patient being compelled to climb a flight of stairs or to perform some light calisthenic movements, when all the symptoms of insufficiency of the cardiac muscle to overcome the obstruction in the blood-vessels are induced, or in other cases a harsh systolic murmur is heard over the base of the heart, due to thickening of the aortic valve from atheroma. Whether at the base of the valves there is first inflammation and then deposits of salts, or *vice versa*, is still a matter of doubt, but the cause is the traumatism due to the high blood-pressure and the increasing rigidity of the aorta.

When either of the above conditions is reached, the nutrition of the heart becomes insufficient and there is gradual dilatation with regurgitations at the mitral valve, and the case ends as in chronic valvular disease, or life is terminated suddenly by acute dilatation induced by over-exertion or the increased high tension of an acute attack of indigestion, etc.

In the arterial type (*a*) degenerative changes cause the vessel walls to become weakened and unable to withstand the high pressure in them during the stage of compensating cardiac hypertrophy and aneurysmal dilatation of the large and small vessels, or rupture occurs most commonly in the brain (apoplexy); or (*b*) when cardiac powers fail and the current through the narrowed and roughened vessels is slow and feeble, there is clotting (thrombosis) with attending paralysis.

In the renal type coincident with the cardiovascular change there is increase in the urinary water, the specific gravity of the urine is low, but the excretory function is within physiological limits. Later the changes in the blood-vessels of the kidneys progress more rapidly than elsewhere, and the fibrous structure of the kidney participates in the process and the case terminates as one of chronic interstitial nephritis.

The hepatic type presents itself in two forms: (1) in which cirrhosis is part of the general fibrotic process; (2) in which there is disturbance of function, and glycosuria, at first intermittent, becomes the determining cause of death.

The arthritic or true gouty type may show itself in various forms. Those with marked heredity may, during early life, be subject to sick-headaches which in early adult life become less frequent and are replaced by attacks of acute gout. The attacks of gout become more frequent and gradually involve a greater number of joints, and a characteristic feature is, that although a joint may have been affected repeatedly, there is very little deformity. Sooner or later attacks are almost continuous, but milder or subacute in character. The inflammatory process passes from one joint to another during each attack until all the joints of the body, which have been "gouty" in any other attack, are involved. The involvement of a number of joints in rapid succession has caused this form of gout to be associated with rheumatism under the term rheumatic gout.

In other forms the articular symptoms are complicated with deposits of the biurate, forming massive tophi and marked deformity. In the arthritic type the changes in the heart, blood-vessels, kidneys, or liver may progress relatively very slowly, but life is generally terminated by changes in these organs, and not by the uric acid deposits.

Which one of the above types will be the terminal stage is determined in each individual by habits, mode of life, heredity, intercurrent diseases and toxæmias.

As practising physicians the questions that are of vital interest to us are:

What is the origin of uric acid?

What is the relation of uric acid to the symptoms of gout and lithæmia?

In what way do food, habits of life, and heredity act as etiological factors?

The theories concerning the origin of uric acid and its relation to gout and lithæmia are many and have changed from time to time with the advances in physiology and physiological chemistry.

Until recent years uric acid was believed to be a result of metabolism of all the proteids and an intermediate product in the end production of urea.

Haig and his followers believe that uric acid is introduced as such with the proteids of animal food and that little, if any, is elaborated during metabo-

lism and that its presence in the blood produces many manifestations.

Lately, with the advance in physiological chemistry, the subject has been studied anew and a much clearer insight gained, although many points are still obscure. The present generally accepted theory is that uric acid is derived from substances in the nuclei of the cells—the nucleoproteids—which by successive cleavage (decomposition) break up into albumin and nuclein, nucleinic acid and the xanthin bases, also called purin or alloxuric bases. The possible end oxidation product or one of the end products of these bases is uric acid.

The nucleoproteids that produce uric acid may come from two sources, first that due to the breaking down of the cells or cell nuclei of the organism itself. The uric acid resulting from metabolism of the tissues of the body has been called endogenous. It has been found that when all nucleoproteids are excluded from the diet—that is, a person is on a nuclein free diet—the output of uric acid falls to much below the normal and remains stationary at that point, although the diet may be rich in proteids that do not contain cells or their derivatives, the purin bases.

It has also been found that the amount of endogenous uric acid that is secreted on a nuclein free diet varies with individual. This indicates that the rate of cell destruction and the resulting output of uric acid is an individual factor in metabolism and varies according to the amount of exercise or rest, but is constant for that person under varying conditions of life, even though the patient is not in a condition of nitrogen equilibrium and the amount of nitrogen taken into the body varies greatly. In a normal individual the endogenous uric acid is not influenced by general metabolism.

The other source of the nucleoproteids is from the nuclein or purin bases taken with the food, especially those articles which are composed of the glandular organs, etc. The uric acid formed from nucleoproteids of this source is called exogenous uric acid.

Of the nitrogen of the purin bases, whether in the form of hypoxanthin of calve's liver, of guanin of the pancreas or the adenin of the thymus, approximately 50 per cent. appears in the urine as uric acid. The trimethyl xanthin or caffeine and the dimethyl xanthin or theobromin cause no increase of uric acid but appear in the urine as such or as purin derivatives.

What becomes of the other 50 per cent. of the nitrogen contained in the purin bases is not known, although it is generally believed that the major part is converted into urea. It has been found that the liver of dogs can convert uric acid into urea. The kidney and muscles of herbivora have the same power, and Mendel has found that in dogs it is converted into a higher oxidation product known as allantoin. Where the purin bases are decomposed or oxidized and what are the successive products between these bases and the final result, uric acid, is still a matter of conjecture.

Experiments seem to prove that the liver is the organ chiefly concerned in the elaboration of the purin bases and also in the further oxidizing of uric acid to urea. Almost equal power has been conceded to the spleen, while the same processes may occur in the thymus and the voluntary muscles. It also seems that when one organ, as the liver, becomes, for any reason, incapacitated for this work, the other organs mentioned, and possibly some others, are able to do extra duty. It has even been claimed that the decomposition to uric acid is not completed in these organs but the intermediate products of the purin bases are brought by the blood to the kidney and there synthetized into uric acid and in certain diseased conditions this ultimate stage can occur in other portions of the body and produce uratic deposits.

These facts have important bearing on the pathology of uric acid, for they show that uric acid is not an absolutely end product of the nucleoproteids, and that a large amount—50 per cent. for the exogenous purin bases and probably an equal amount for the endogenous—is converted in the organism into urea or some product more highly oxidized than uric acid.

In any theory put forth to explain the accumulation of uric acid in the body and the production of gouty condition, the fate of this unaccounted for purin base-nitrogen must be taken into account. For it has been found that when uric acid is injected subcutaneously in man, only 50 per cent. is eliminated in urine. In testing the urine to determine the amount of purin gases eliminated, the uric acid alone cannot be taken as the index; for purin bases themselves or their derivatives may be present in the urine. Uric acid should always be considered in connection with the amount of these substances in the urine.

In order to explain fully the relation of uric acid and its increase formation or retention in the body to the symptoms of gout and lithæmia, it is necessary to have more definite knowledge on, First: the physiological and pathological conditions which may increase the production of endogenous nucleo-proteids from increased tissue metabolism. Second: All the forms in which the nucleoproteids are introduced with the food. Third: The power of the tissues to decompose the purin bases into uric acid or still further change them into urea or some form beyond uric acid. Fourth: The effect of the purin bases or the products intermediate between them and uric acid, on physiological and pathological processes. Fifth: The factors that cause its accumulation in the tissue in the form of urate of sodium and the production of the gouty condition. Sixth: The factors that prevent the elimination of uric acid in normal amounts. Seventh: The factors that cause separation of uric acid from the urine in the kidneys and bladder.

With regard to the symptoms that attend an attack of gout the "mechanical" theory offers a sufficiently satisfactory explanation. In brief, this theory is that the local manifestations of gout are due to the precipitation of fine, needle-like, crystals of biurate of sodium in the fibrous and cartilaginous structures in and about the joints. These crystals cause irritation in the same manner that any foreign body of a similar form, as, for instance, fine spun glass would if injected or showered into these same structures. The intensity of the inflammation, pain, and swelling are in proportion to the amount of precipitation, the density of the structure of the tissues involved, and the effect of the inflammatory swelling.

What the local conditions are that cause the precipitation of the crystals of biurate of sodium, and what is the form and what the combination of uric acid prior to crystalization, is a mystery, although numerous theories have been brought forth to account for it.

Garrod believed that it was due to lessened alkalinity of the blood and inability to hold uric acid in solution.

Haig claims that gouty deposits and symptoms of lithæmia depend on varying alkalinity of blood.

Roberts holds uric acid circulates in blood as quadriurate, and as such is voided by kidneys. In the gouty state there is an accumulation in blood either from defective elimination by the kidneys or

excessive introduction of urates in the blood. In those portions of the body where fluids are rich in sodium carbonate, the quadriurate is precipitated as biurate, first in a hydrated or gelatinous form, which later passes into crystalline condition, and that the precipitation is influenced by (*a*) temperature, (*b*) quantity of uric acid in solution, (*c*) saline substances.

Ebstein thinks there is first a nutritive tissue disturbance which leads to necrosis, and in the affected areas the urates are deposited.

As the exact seat of the formation of uric acid is still undetermined, it is a question if uric acid cannot be synthetized in the tissues where it is found precipitated, as it is conceded that it can be oxidized in various tissues and organs of the body.

The "mechanical" theory has also been deemed sufficient to explain many of the symptoms of lithæmia, especially the neuralgias and some of the effects on the blood-vessels. It has been claimed that in the nerve structures and blood-vessels there are slight precipitations or showers of uric-acid crystals which produce the varying type of pain and reaction. This theory is insufficient to explain all the conditions of acute and chronic lithæmia.

Other investigators claim that the diverse symptoms of lithæmia are due to toxæmia. That uric acid is not found as such in circulating blood and lymph, and that in the form of biurate of sodium it is found only in certain structures of the body where precipitation has occurred.

Are there any facts to substantiate the theory of toxæmia, and do the recent investigations of the physiological chemist throw any light upon the subject?

The fact that uric acid is derived from nucleoproteids only, and is not an intermediate product between all forms of proteid and urea, has limited the part it plays in general metabolism.

The relation of uric acid output to the occurrence of leucocytosis has raised the question whether the factors that increase the activity of the lymphatic tissue (organs) might lead to the accumulation of nuclein, which sometimes results in the increased production of leucocytes, and at other times only in an increased production of alloxuric bodies through their cleavage or oxidation.

That alloxuric bases when taken as food or when injected into the body subcutaneously can produce symptoms, is proven by the experiments of Berian and Schur. Arthur R. Mandel, in a recent communication (The Alloxuric Bases in Aseptic Fever, *American Journal of Physiology*, Vol. X, No. VII), has shown the relation of the increase of the alloxuric bases and decrease of uric acid in the urine to the leucocytosis and temperature range in aseptic fever. He also showed the influence of subcutaneous injection of xanthin on the monkey, and of taking by mouth of large doses of xanthin base in the form of caffeine on the human subject.

While we know that the xanthin bases are the anticedents of uric acid, the physiological chemist has not been able to trace all the changes that occur between them and uric acid; and we have no knowledge of the physiological and pathological effects of the intermediate products when they occur during normal or abnormal metabolism or when they are retained in the body.

Everyone concedes that food, habits of life, and heredity have an important bearing upon the production of gout and lithæmia. Two or more of these factors may be necessary to induce them in some cases; in others only one is present. The articles of diet that have the greatest influence in producing the clinical manifestations of gout and lithæmia are the animal proteids and alcoholic beverages. In meat the nucleoproteids are the only source of exogenous uric acid, as very little free uric acid is found in the meat itself. The fermented liquors also introduce a certain amount of xanthin bases. The most marked influence of these articles of food and drink is the production of endogenous uric acid from tissue change. The examination of the urine shows that, after a meal, the height of uric-acid secretion precedes that of urea, and the amount of uric acid bears a definite relation to the degree of digestive leucocytosis. Whenever the amount of food, of whatever nature, overtaxes the digestive capacity of the individual it is apt to produce definite gastrointestinal disturbances, as nausea, vomiting, or diarrhœa, which are self-curative. When, however, this excessive alimentation does not produce these symptoms, the effects may fall upon other structures, overtaxing their functional capacity and influencing the processes of metabolism and producing a definite toxæmia, which may or may not be attended with leucocytosis, and the symptoms of this condition are very similar to that of acute lithæmia.

We are all familiar with the fact that habits of life have an important influence on the production of gout and lithæmia. With an outdoor life and free muscular exercise, immense quantities of animal food and even alcohol can be taken without causing a corresponding increase in the amount of uric-acid secretion, and this same mode of life is frequently sufficient to remove the symptoms of lithæmia. It has been proven that only about 3 per cent. of the nitrogen of the nucleoproteid appears in the urine as uric acid, and that the remaining 50 per cent. is probably oxidized into urea or some other product. When the processes of metabolism are normal and sufficient to elaborate all the food taken with an outdoor life and free muscular exercise the oxidation of the purin bases both exogenous and endogenous, probably occurs not only in the liver and spleen but also in the muscle tissue, although this fact has not been absolutely proved.

Heredity is a most important factor in the occurrence of gouty condition. More than 50 per cent. of all cases showing these symptoms give a family history of gout. As I have stated elsewhere family resemblance or likeness is not limited to outward forms and features alone, but every tissue of the body bears the impress, and the nutritive processes follow the groove worn deep by preceding generations, and family tendency (heredity) shows itself earlier in each succeeding generation, unless checked by treatment or modified by the introduction of new tendencies. The special family weakness may be an inactive liver, kidneys unable to adapt themselves to the extra demands of a particular mode of life, a digestive apparatus that while it tolerates an overabundance of food is unable to elaborate it fully, an irritable sympathetic nervous system that responds inordinately to slight disturbing causes. The tendency of the vital processes to be disturbed by the ordinary wear and tear of life, or to be influenced unduly by accidental circumstances, acute disease or toxic agents, early causes disturbance of the cardiovascular system. The increased arterial tension and the pathological changes of arteriocapillary fibrosis that frequently occur early in life as the result of many infectious processes and at other times by alcohol and lead, would indicate the existence of some toxic agent in the blood as the primary cause in all cases.

Just what this toxæmia is we cannot at the present say, for it is impossible to follow all the steps of constructive and destructive metabolism, but certainly we have no right to decide that it is due to uric acid circulating in the blood.

What we do know from clinical experience is that it is dependent on a want of balance between the amount of food taken and the powers of metabolism to elaborate and oxidize it in a normal manner.

Lithæmia should be considered an expression of more or less profound disturbance of the metabolism, and our aim should be to find out at what point the disturbance occurs and what has induced it. Uric acid over-production, its retention in the body, its precipitation in the tissue, and the secondary pathological changes induced by it, are merely incidents in the course of this disorder of metabolism and nutrition.

52 West Fifty-sixth Street.

INSUFFICIENTIA PYLORI.*

By MARK I. KNAPP, M.D.,
NEW YORK.

Too long has the unfortunate opinion prevailed that a chronic dyspeptic is doomed to lifelong misery, if not, indeed, to suicide, which, quite often, is the finale to a tragic existence. The recognition of insufficientia pylori as one of the causes of chronic dyspepsia is of paramount importance, as it leads to almost miraculously quick improvement. This is my opinion, based on over fifty consecutive and successful cases.

One hour after Ewald's test-breakfast (I shall use here test-meal and test-breakfast as synonyms) the healthy stomach should yield from 30 to 50 c.c. of chyme, the solid part of which should be well pulverized and the fluid part should be quite thin. The chyme should readily filter. Not always, however, do we meet such conditions. There are pathological variations on either side of the normal, both as to quality and quantity.

Insufficientia pylori is the condition in which nothing or possibly but 1 or 2 c.c. of chyme are aspirated one hour after the test-meal, this, because the pylorus either does not close at any time or does so insufficiently for a shorter period than is normal. I shall beg your indulgence if I begin with the cause of the physiological, clonic closing of the pylorus on introducing anything into the gastric cavity.

The presence of matter in the stomach causes its muscular fibers to contract; the degree of such contraction being in direct relation to the degree of the irritant. Normally, the exciting cause is not so great as to throw at once the entire stomach into one convulsive contraction, but the contraction begins at the fundus and travels toward the pylorus. Whilst the band of muscle fibers "B" contracts, the band "A" begins to relax. These successive contractions we call peristalsis. Let me say here, in parenthesis, that respiration has a decided influence upon peristalsis; inspiration aids the motility of the stomach. When the peristaltic waves finally reach the end of the stomach, the pylorus, this likewise contracts, the same way as does the stomach. But, although the cause and the mechanism are identically the same, the effect upon the pylorus is different from that upon the stomach in general. The same cause and the same degree of contraction which produces in the stomach cavity but a diminution of its diameter, causes in the pylorus its entire occlusion. This is very readily explained by the difference between the diameter of the stomach cavity and the narrow lumen of the pylorus. The pylorus having a very small diameter needs but little contraction to occlude its entire lumen. No difference of force, cause, or mechanism is required to explain the physiological, clonic closure of the pylorus during gastric digestion. What produces general gastric peristalsis also produces closure of the pylorus; the closing of the pylorus must not be regarded as anything else than ordinary peristaltic contraction. Starting from these normal physiological premises we can reason that what will cause greater general contraction of the stomach will so much more intensify the closure of the pylorus. But as the general stomach cavity has a considerable lumen to contract upon, whilst the same aggravated contraction reaching the pylorus, has nothing more to contract upon than its own anatomical structures, it is evident that such anatomical structures will suffer the consequences of such repeated and spastic contractions. Our knowledge of inflammation, its causes and its manifestations, would at once make us anticipate inflammatory changes of the pylorus under the conditions just mentioned. But besides this, which I might call intrinsic cause, there is the additional element of the violent impact of the chyme which is thrown against a closed pylorus by the aggravated contractions of the muscle fibers of the stomach. Thus, we see two forcible factors for the production of inflammation of the pyloric portion. This explains the fact why autopsies show, in by far the largest majority of cases, only the pyloric portion to be the seat of lesion. In fact, I believe we should be justified in discarding the name of gastritis in the majority of instances and substitute the name of pyloritis instead.

The muscularis of the stomach, naturally, has a muscular, hence a dynamic function, and, in accordance with the work to be performed, varies its development. In the grain-eating birds, for instance, the muscular layer of the stomach is enormously developed, because the grains have first to be crushed before they can be acted on, chemically, by the digestive secretions. Likewise in man does the stomach complete the grinding, begun by the teeth. This is a fact which is attested by the very finely pulverized chyme, so often aspirated from the stomach. But, is this very finely pulverized chyme really the result of only dynamic, of only muscular activity? Yes. And this affirmative answer can be verified by both direct and indirect ways. I have many times experimented with artificial digestion and, although I did obtain all the chemical results, I never did get the solid part finely pulverized until it was thoroughly stirred up with a clean glass rod. The clinical proof presented itself to me in a case of pyloric stenosis in which I first ascertained that the stomach was empty before I gave the ordinary test-meal. One hour after it I aspirated the entire ingested meal and, notwithstanding that the general acidity was as low as 18 (even dimethyl scarcely reacted), the ingested roll was recovered in a very finely pulverized form. On the other hand there are abundant clinical instances in which the chyme is coarse, although there are sufficient acid values. These facts I consider beyond doubt to be entirely conclusive, that finely pulverized chyme is the result of mechanical crushing. Crushing implies that the object to be crushed must come between two opposing forces—the driving and the resisting force. In the stomach the contracting muscle fibers represents the driving and the closed pylorus the resisting force. The stronger these two forces act

*Read in abstract at Albany before the Medical Society of the State of New York, January 26, 1904.

upon another, or the longer the grinding continues, the finer pulverized will be the crushed product. Again, the finer the pulverization the longer or the stronger was the muscular contraction and the longer did the pylorus offer resistance. We therefore must admit that to obtain a very finely pulverized chyme the ingesta must be subjected to the action of the forces mentioned, sufficiently long, which means that the ingesta must remain in the stomach long enough to be acted upon, dynamically, by the muscular contraction of the stomach. In the same manner the aspiration of a chyme which presents the very fine pulverization, termed by me the "floury layer," attests the existence of at least normal, if not hypermotility of the stomach, and this irrespective of the quantity aspirated. Nay, as it needs a prolonged contraction of muscle fibers also of the pylorus, as it needs a longer closing of the pylorus to produce the "floury layer," it is evident that the closed pylorus also prevents the passing of chyme into the intestine; hence a larger quantity will be aspirated. The larger the quantity and the finer the pulverization the longer did the pylorus offer resistance, the longer was the pylorus closed. Since, however, a protracted closure of the pylorus could not exist without active peristalsis (as explained above), and since a prolonged closure of the pylorus obstructs the escape of chyme and hence leaves more chyme to be aspirated, it follows that the aspiration of a large quantity in which the "floury layer" is present signifies that in such a stomach peristalsis was very active. This is a view diametrically the reverse of what is at present recognized. We are taught that a stomach which yields a large quantity of chyme after the test-breakfast is atonic. We have been made to believe that the presence of a large quantity of chyme after the test-meal incriminates the integrity of the muscular power of the stomach; it is being assumed that because the ingesta did not pass the pylorus in sufficient quantities in the given time it is ample proof that the stomach wall, for some reason or other, has not attempted to expel its contents. With the same propriety we might accuse the prisoner of not attempting to come out of his cell. Supposing the cell is locked and bolted and all efforts of its inmate to get out of the cell are frustrated because of the door being locked? The tonus of muscular fibers is judged by its respective power. But, when we aspirate a "floury layer" such facts prove muscular activity. To accuse a stomach, which yields after a test-breakfast a large quantity of chyme of which the solid part is very finely pulverized, of atony is a crime. Such stomachs are not only not atonic, but the very contrary, they are *hypertonic*. The large quantities aspirated in such cases is due to the stenotic condition of the pylorus. This stenosis is, most usually, due to a pathologico-chemical condition, and which I described as "stenosis pylori ab irritatione." It is peculiar and possibly significant that both, Boas and myself, have independently worked on the same theory at the same time. Boas, in article on "Magensteifung" (*Deutsche medizinische Wochenschrift*, March 6, 1902), also refutes the present assumption that the aspiration of a large quantity of chyme after the test-breakfast signifies atony. He also acknowledges a stenosis pylori as the cause of the large aspirated quantity. I again wish to impress that quantity does not impugn the integrity of the muscular coat of the stomach one way or the other; quantity is dependent upon the respective condition of the pylorus. A prolonged contraction of the pylorus offers prolonged resistance to the escape of chyme from the stomach, hence a larger quantity will be aspirated. A pylorus, the contraction of which is lessened or entirely abolished offers little or no resistance at all to the exit of the chyme, hence a much larger quantity of the ingesta will pass the portals of the intestines unmolested, unchecked, and hence little or no chyme at all will be obtained on aspiration. There is no increase of motility in this condition, as there is no impairment of the muscular activity when a large quantity is aspirated. *The absence of chyme one hour after the test-breakfast cannot be ascribed to hypermotility*, as hypermotility means hyperactivity, which is synonymous with hypercontraction, and hypercontraction, as explained above, must produce more spastic contraction of the pylorus. Hypermotility of the stomach, therefore, effects larger quantities to be retained in the stomach. *The presence of a large quantity of chyme after the test-meal means stenosis, the absence of chyme denotes "insufficientia" pylori.* But very little peristalsis is necessary to bring ingesta past an open pylorus, mere gravity will do it. Furthermore, the absence of pyloric resistance has a decided negative effect upon the grinding up of the ingesta. Because of the absence of one of the two forces mentioned above as necessary for the grinding, because of the absence of pyloric resistance by reason of its non-closure or insufficient closure, the ingesta cannot be acted on dynamically, and therefore it is that whatever little is aspirated in the first stages of insufficientia is coarse.

Insufficientia pylori presents itself in several stages. It begins with a simple weakness, if I may use this expression, when possibly yet 1 or 2 c.c. of coarse chyme are aspirated and ends with its complete inability to contract. In this last stage the ingested food rushes immediately past the pylorus, the patient practically has no stomach. Between these extremes there are many gradations. We may not find any chyme at the end of one hour, but there may be some, three-quarters, or half, or one-quarter of an hour after ingestion, and it is our duty to absolutely ascertain the exact condition.

Etiology.—Insufficientia pylori is the natural and logical successor to stenosis pylori (I am not speaking here of the stenosis of an organic nature). It is but a question of time when the pylorus, too long insulted by spastic contractions and by the violent impact of food, together with other, chemical causes will succumb to such maltreatment with the inevitable inflammation as the result. And once this is chronically established, we can easily foresee the consequences. That finally, in the very last stage, anadenia gastrica should result need no surprise. Very seldom is insufficientia pylori the sequel of a retrograded neoplasm as described by Ebstein (*Deutsches Archiv für klinische Medizin*, Vol 26). Directly, insufficientia pylori is caused by a chronic pyloritis. As remote causes are organacidia gastrica (MEDICAL RECORD, September 6, 1902) chronic alcoholism, loss of teeth, and gulping down of food.

Symptoms.—*Per se* insufficientia pylori gives no symptoms, and it may exist for a long time without the patient being aware of it. What the patient complain of is due to faulty intestinal digestion. And, usually, the patients do not seek medical advice before the intestinal functions are interfered with. The most predominant and the most constant symptoms are due to gas formation in the bowels. This is variously interpreted by the patient as boiling, running around, shaking, heaviness, tension, sensation of bearing down, sensation of insufficient defecation. A woman about the climacterium

thought she positively felt "quickening" notwithstanding her menstruation having been regular up to the time of her consultation. The appetite is variable and may be good or absent, but there are definite causes for each. When the gases formed in the intestines are not irritant then the distension causes anorexia. When the gases are volatile fatty acids, then the attendant contractions of the upper part of the intestine due to the presence of such volatile acids, give the sensation of hunger. In the prevailing of the latter contingency, besides the very good appetite, will be diarrhœa, cramps, and rectal tenesmus, and, if the volatile fatty acids make their way through the upper passage, there will be burning along the route and thirst. Constipation is not infrequent, and, I am now inclined to believe, is due to distension of the bowel by non-irritating gases. Often constipation alternates with diarrhœa, the diarrhœa being subsequent to and caused by the constipation. The stagnating fæces finally undergo putrefactive changes with the evolution of irritating gases which then irritate the bowel, thus bringing on peristalsis. Headaches may or may not be present, but as yet I have not been able to ascertain the exact cause of each. The dictum that constipation and headaches invariably go together I cannot corroborate, although it holds good in most instances. Flashes of heat and cold are very common, especially in the evening, after the somewhat heartier meal, which the insulted intestines struggle to digest. It can safely be assumed that one who abused his stomach will also abuse his bowels, if not warned in time. But, often, patients are not aware of serious gastric trouble or of any digestive interference. Occasional "spells" they take very lightly, often as a matter of course. In illustration of this I will cite one instance: A young man, twenty-eight, a travelling salesman, had been coughing for some three years, during which time he consulted several general practitioners without being helped. Finally, alarmed about this cough, he went to a prominent lung specialist, who, after the third visit, came to the conclusion that most likely the cough was caused by some disorder in digestion. The patient then came to me, rather surprised at the lung specialist's finding, as he could not remember any serious attacks of indigestion. That patient's stomach had already advanced to the condition of insufficientia pylori. His cough stopped permanently after the sixth day (he came for treatment every day). Vomiting may or may not be present. Besides those there may also be other symptoms.

Diagnosis.—Insufficientia pylori cannot be diagnosed without a test-meal—nay, several test-meal examinations, one to follow the other one day after the other. Absence of chyme one hour after the test-breakfast or at most 1 or 2 c.c. of coarse particles is the diagnostic criterion. The diagnosis should be corroborated by another test-meal the very following day. In a tentative way the diagnosis may be assumed in cases of chronic alcoholism or in patients with few or no teeth. Neither sex nor age gives any clue. The diagnosis of insufficientia pylori having been made, it becomes our duty to ascertain exactly the patient's condition. The question, and a very important one, is, how soon is the stomach empty? Does the stomach functionate at any time or has the patient practically no stomach? These questions are answered by aspirating the stomach at various times after the test-breakfast is given. If the stomach prove to have no chyme one hour after the test-breakfast, we, next day, aspirate three-quarters of an hour after the ingestion, or thirty, or even fifteen, minutes after the eating. Upon this exact knowledge is based the successful treatment. When the case is properly explained to the patient, he will usually corroborate with the physician. If we can manage it, all real medications should be stopped for a few days before our examinations. Of the physical examination only gastric inflation may be of some avail. In the last stages of insufficiency the stomach cannot be inflated by any means. But one must be careful not to mistake a dilated stomach for insufficientia pylori should he choose for inflation CO_2 developed in the stomach. The usual doses for inflating a stomach are half a teaspoonful each of bicarbonate of soda and of tartaric acid, each to be taken separately and in immediate succession with about two ounces of water. If these do not inflate we need not yet conclude upon insufficiency.

Prognosis.—If not attended by too severe complications, insufficientia pylori has an excellent prognosis, no matter how old the patient is or how long the disease had existed. I have seen the cases in my own practice and in consultation, in which the conditions prompted the gravest diagnoses and in which improvement had been despaired of, respond almost miraculously to the proper treatment. A marked turn for the better is positively seen in a very few days, often even within a day or two after treatment has been begun. Patients who have suffered for years from chronic dyspepsia get well, gain flesh and change their melancholy into buoyancy and optimism in a very short time. Thus I had among my patients a colleague about fifty years of age, who until recently taught diseases of the stomach and who had to give up his position because of ill health, greet me on the twelfth day after the test-meal examinations with a hearty handshake, a broad and cheerfully smiling "How do you do" and a slap on my shoulders. This greeting needed little interpretation. My esteemed colleague had not a trace of chyme even half an hour after his test-breakfast. The usual average for the treatment has proved to be about three months. Often the patients are inclined to overbear, exhilarated by the rapid success, and are tempted to do a little experimenting themselves. Against this the physician must guard. A return of the pylorus to the normal can only be expected in the young; I have seen this several times.

Treatment.—As everywhere else, the etiological moment must be kept in mind. Alcoholism and gulping down of food will, naturally, be interdicted. It is much better to go without food than swallow it down unmasticated. If circumstances do not allow the patient sufficient time for his meal then let him have such food that needs no mastication. Mastication must at all times be complete. Loss of teeth must be supplanted by artificial ones. Especially to the poor must we explain the necessity of thorough mastication. But as they cannot always get a set of good artificial teeth we must advise them to have the mastication done artificially. All cereals and vegetables should be well boiled and eaten in the form of puree. As to meat, my advice is to prepare it in any way they like, and after it is done to cut it up into very small pieces, which is best done by a meat-grinding machine, which is very cheap.

The dietetic treatment is of chief importance. The object is, not to introduce any acid food nor food which develops gases. Let us also remember that sweets very quickly form acids in the digestive canal, consequently, also, these will be omitted from the dietary. Coffee, tea, spirits, fermented liquors, CO_2 containing waters, too much milk, cabbages, peas, beans, radishes, turnips, spices, salads, fruits, especially grapes, peaches, plums, and prunes should

be forbidden. Excluding these, the patient has a free choice of food but not of drink. Clean, filtered water and milk are about all the patient can have. Of mechanical treatment only lavage is to be mentioned if mucus is present; I have as yet not tried electricity.

The medicinal treatment must be directed to help the intestine, but at the same time not to interfere with any gastric digestion, which may still be present. It is for this reason that several test-meal examinations are necessary. We must know whether the stomach does have some digestion, and if so, we surely must not interfere with it by giving the alkalies too soon. Bicarbonate of soda, magnesia, and the rhubarb and soda mixture are usually sufficient and to be given after meals, the time to be determined by the test-meal examination. So, for instance, if there is no chyme, even fifteen minutes after ingestion of the test-meal, then the alkalies should be given immediately after meals. If there is some gastric digestion yet half hour after the test-breakfast then the alkalies will be given between half an hour and one hour after meals. If there is some gastric digestion still present the alkalies should be given somewhat later when meat is eaten. Pancreatin and papain are very valuable, but we must be sure to get the fresh products; stale products are very apt to be decomposed and cause pain, colics, and diarrhœas. Strychnine is the drug never to be left out, but it must not be given in small doses. I never begin with less than one-twenty-fifth of a grain. Especially in the chronic diarrhœas has the strychnine a magic effect. Cases in which there were daily ten to twenty watery discharges and which have lasted for years, in one case over eight years, have yielded entirely and permanently to strychnine in from three to four weeks. But in these cases the strychnine must be given in rapidly advancing doses; I repeatedly gave one-seventh of a grain three times daily.

For constipation sodium sulfate and liberal quantities of water are of most benefit. The sodium sulphate should be begun with one-half teaspoonful doses in a glassful of hot water half hour before meals; this dose should be diminished gradually according to requirements. When the drinking of large quantities of water is desired it is best not to tell this plainly to the patient, as he will usually disobey. Any sort of drugs, and by far the best impressive, are bitter drugs, can be given in drop doses every two hours in a tumblerful of water.

In conclusion, I want to refer to my previous articles on insufficientia pylori in the *Philadelphia Medical Journal*, May 24, 1902, and in the *New York Medical Journal*, October 4, 1902.

HEMORRHAGE AFTER TONSILLOTOMY; ITS GENERAL CONSIDERATION.*

By H. JARECKY, M.D.,
NEW YORK.

VISITING OTOLOGIST, HARLEM HOSPITAL; EYE, EAR, AND THROAT SURGEON, SYDENHAM HOSPITAL; ASSISTANT SURGEON MANHATTAN EYE AND EAR HOSPITAL, ETC.

When we consider the blood supply of the tonsils, their close proximity to large blood-vessels, and the frequency with which the operation of tonsillotomy is performed, we must wonder at the small number of mishaps reported.

A review of the past sixty-one years, that is accepting Dr. Damiano's statement,[1] and bringing the account to date, places the number of post-operative hemorrhages reported at one hundred and seventy-five. A systematic search reveals two authentic fatal cases in which the operation was performed according to modern technique. One was Damianos' own patient, age twenty-three years, who died sixteen days after the operation from repeated hemorrhages and an abscess resulting from subcutaneous injection of gelatin, probably a hæmophiliac.

Barkan[2] reports a fatal secondary hemorrhage in a six-year-old boy after using tonsillotome and Gottstein curette for the tonsils and adenoids. The bleeding had stopped, and recommenced two and a half hours later when the child began to cough and scream. Clots were vomited. Ether was then administered and the whole parts cauterized. On awakening, slight bleeding from the nose appeared. An attempt to open the mouth for examination caused the child to struggle, scream, a fresh hemorrhage, and sudden death of the boy. There are other cases[3] related, resulting from operative interference in other conditions, but the paper only deals with the chronic hypertrophic faucial tonsils. During my practice of the past seventeen years, I have had and seen several cases which were controlled. These I shall relate in various parts of this paper.

To avoid and arrest these hemorrhages we must first examine the causation, secondly, select the best method of operating, and, thirdly, know how to control them.

1. The causes of the bleeding are (1) hæmophilia, (2) fibroid tonsils, (3) laceration of blood-vessels, (4) anomalous arteries, (5) wounding of the anterior pillars, (6) ulceration.

1. In *hæmophiliacs* we all know what may happen, and so I invariably ask before operation whether such a condition exists; always framing the question so as not to alarm the patient or friends. I think we are justified in refusing to operate on these patients unless in extreme emergency. However, at times the fact will be concealed,[4] as the following case illustrates: A young man, aged twenty-one, whose tonsils I removed under anæsthesia, remained at my office until the bleeding stopped. Five hours later I was called to his house. He was almost exsanguinated, bleeding, and vomiting, and withal so nervous that he presented a sorry plight. With a good illumination I inspected and cleaned the parts and found a general oozing. To this I applied pressure with a pad of sterilized gauze on the end of a forceps. In about twenty minutes the bleeding stopped; and, after remaining one-half hour longer, I returned home. I left instruction with the brother—an experienced druggist—to reapply the pad, soaked in adrenalin if necessary. Four hours later I was summoned again, the hemorrhage being uncontrollable. This time I applied the Stoerck-Mikulicz tonsil hæmostat. As there was no recurrence, I removed the instrument the next day. Many months elapsed ere the young man regained his normal condition. Although I inquired carefully, yet I did not learn that he was a hæmophiliac until after the operation.

2. *Fibrous tonsils.*—We can safely regard it as a good rule that after the eighteenth year the hyperplastic changes that have taken place in a tonsil that has been the seat of repeated inflammation cause the interstitial fibrous tissue to increase and prevent the retraction of the blood-vessels. This explains why hemorrhages rarely occur in children.

3. *Laceration of Blood-vessels.*—When the vessel has not been clearly divided while operating, the contractile power of its coats is interfered with. This is well shown in the following case: I was called by the family physician to see a girl, aged ten, who had been bleeding intermittently for a number of hours after a double tonsillotomy. He informed me that the right side caused no trouble, and that he had used various astringents, including persulphate

*Read before the Harlem Medical Association.

of iron, without permanent effect. On examination I found the right tonsil to have been completely excised; but the left one, after clearing away the grumous mass caused by the iron and blood, only partially removed. From the upper surface I noticed a spurting blood-vessel cut slantingly. This I twisted with a long narrow forceps and the bleeding ceased. Fortunately, the patient was very tractible and so the task was comparatively easy.

4. *Anomalous Arteries.*—While these cannot be foretold, yet an examination of the removed tonsil may show the position of a large artery, and proper treatment may be given immediately.

5. *Wounding of the Anterior Pillars.*—This can always be avoided by separating them from the tonsil by means of a blunt hook, or by a knife specially made for that purpose. The bleeding from wounding the pillars is slight, but usually persistent. I have had two cases referred to me. These I controlled with the galvanocautery. This accident invariably intensifies the feeling of sore throat which exists after tonsillotomy.

6. *Ulceration* is usually the cause of secondary hemorrhages. After operation the parts should be sprayed with some mild solution, as, Seiler's, Dobell's, glyco-thymoline, boracic acid, etc. The feeding is very important; nothing should be taken that will scratch the wounded surface or that is in any way difficult of digestion and liable to produce vomiting, thus perhaps reopening the closed vessels.

The best method of operating in any given case will naturally lessen the chances of hemorrhage. Let us briefly mention the various methods: (1) The bistoury. (2) Laying open crypts with a sickle-shaped knife, and either destroying the parts with chemicals or excising with the tonsil punch. (3) The tonsillotome, either with or without the fork, to draw out the tonsil. (4) The cold snare. (5) The galvanic écraseur, the galvanocautery and Paquelin's cautery.

1. With the bistoury and tenaculum method I have no experience; but it seems to me that it would be very liable to injure the pillars and the tongue. A number of accidents have been reported from its use. I do not think it is much used in this country.

2. Laying open crypts and destroying with chemicals or tonsil punch. This is sometimes satisfactory where the crypts are exceedingly large and filled with secretion or calcareous particles.

3. Amputation with the tonsillotome is certainly the humane method of operating, and is especially applicable to children, who form the mass of our patients.

4. The use of the cold snare is excellent for fibrous tonsils.

5. The galvanic écraseur, as well as the galvanocautery and the Paquelin cautery, can also be used for fibrous tonsils, but one or the other is always indicated when a hæmophiliac is operated upon, and tonsillectomy is performed.

After all methods of operating, cases of bleeding are reported. Thus Roy[6] reports a secondary hemorrhage in a child aged four—McKenzie's tonsillotome having been used—and S. J. Knapp[7] of Indiana reports one in a child aged twelve—tonsillotome having been used. Gradle[8] reports a case in a gentleman aged thirty after hot snare. Ryan[9] reports two severe cases after McKenzie's tonsillotome and the cold snare, in young adults. Ingalls[8] also reports one after cold snare in a child and Bosworth[9] one after the galvanocautery.

I herewith report a case after the use of the Mathieu tonsillotome. A girl, aged seventeen, was operated upon under anæsthesia at the Sydenham Hospital. One, a buried or so-called submerged, tonsil was removed, as well as some adenoid tissue from the pharynx. She remained in bed at the hospital for a number of hours; then, feeling well and not bleeding, returned home. Early next morning I was called in a hurry and found that she had been bleeding the evening before and vomiting clots of blood, until she arose to walk across the floor, when she fainted and the bleeding stopped. Upon inspection, I found a large, firm clot at the side of the tonsil. No hemorrhage seemed to have taken place from the vault of the pharynx. As there was no bleeding, I did not disturb the clot. I ordered the patient to remain in bed, fluid diet, quiet, and to avoid clearing of the throat. On examination, two days later, I found long strings of the clot hanging in the pharynx and causing irritation. These I cut from the main clot but there was no oozing. On the sixth day there was a slight recurrence of the bleeding and on the eighth the clot separated. Undoubtedly the bleeding was venous—from an injury to the plexus of veins at the base of the tonsil.

H. M. Thomas[10] reports similar case of hemorrhage seventy hours after operation.

Another case, a mild one, occurred in a physician aged twenty-two from whom I removed the left tonsil at my office. Adenectomy had been performed on a previous occasion without any annoyance. No local hæmostatic was used. He remained until the bleeding ceased. About six hours later I was informed that he had been bleeding for two hours and was quite weak and faint. Gargling with ice-water and peroxide of hydrogen was ordered and controlled the bleeding. There was a recurrence for two hours the next day.

Control of the Bleeding.—The bleeding ceases usually spontaneously in a few minutes after the operation. If it continues, it must be stopped. In every case, even if an anæsthetic be required, the parts should be cleaned and a good view obtained, separating the pillars with a bent probe. This informs us of the character of the bleeding, as to whether it is a capillary, venous, or arterial, and measures can be adopted accordingly. Locally, for mild cases, ice, a paste of tannic and gallic acids, a saturated solution of adrenalin may be used. The perchloride of iron makes such a thick black mass, that I do not favor its use. Internally, suprarenal extract, ergot, or gallic acid can be employed. If the bleeding is severe in an unmanageable patient, a hypodermic of morphine acts often like a charm. If one or two vessels cause the trouble, they should be seized with a forceps or a tenaculum and twisted. If the bleeding is from the whole surface of the tonsil or venous oozing, the Paquelin or the galvanocautery should be applied. Sometimes direct pressure with gauze-wrapped thumbs for about half an hour will stop the mischief. With some patients, highly excitable, vomiting, bleeding, it is very difficult to do anything—but here nature helps us—for, as soon as fainting takes place, the hemorrhage ceases. So, at times, it may be good to promote syncope, having the patient sit or stand. Sometimes the remaining stump can be drawn forward and encircled by a ligature, using a transfixion needle if necessary —or passing a purse-string[11] suture around and drawing it together. A good method is to pass two ligatures from the posterior pillars, through the anterior ones, and tying each so that the tonsil is folded on itself or else makes a good recess in which to pack gauze. The tonsil hæmostat is an excellent instrument by which pressure can be made over the tonsil with one part and the other at the angle of the jaw by means of a screw and then left *in situ*.

Ligature has been applied to the common internal and external carotid with varying success. Which

vessel should be tied is a question that may occur. Each tonsil is separated by the superior constrictor of the pharynx and its aponeurosis from the internal carotid and the ascending pharyngeal branch of the external carotid. The latter is very close to the tonsil, but the internal carotid is really out of the way from danger of being wounded with a tonsillotome.

The external carotid artery is not far from the outer surface of the tonsil, and the facial is almost always in close connection with its front border, where it furnishes the tonsillar branch, which is the vessel most apt to give rise to troublesome hemorrhages. It would seem that the external carotid, whose branches supply the part, would be the one to tie.

Burkhardt[12] recommends, as a last resort, in the rare cases in which everything has proved ineffectual, to cut down on the tonsil through an external incision and secure the bleeding points. This, I should judge, is a rather complicated procedure.

In concluding this paper, I would draw attention to the following:

1. That troublesome hemorrhages occur in children.
2. That they happen very frequently in adults, in proportion to the number operated upon.
3. In case of bleeding, use a good light and clean the parts to ascertain the cause.
4. Anæsthetize or use morphine, if necessary, to quiet the patient.
5. Never operate without being prepared to cope with a hemorrhage.

The Etiology of Rickets.—In summarizing the results of some experimental work, R. G. Freeman states that experiments on animals would seem to indicate that unsuitable food is capable of producing rachitis and that possibly certain bacteria or intestinal toxins may produce a similar result. His clinical observations are too limited for any positive deductions, but are interesting inasmuch as they indicate less rachitis in the tenement than in the institution children fed on modified milk, and the greatest amount of rachitis in institution babies fed on breast milk with auxiliary feedings of condensed milk.—*Archives of Pediatrics.*

Gymnastics in Paralysis Agitans.—R. Friedlander reports the results of his endeavors to apply certain gymnastic methods to the treatment of this affection which have met with a considerable degree of success in alleviating the symptoms of this disease and checking to a certain extent its course. Any exercise which calls for muscular exertion must be avoided just as in tabes or any other disease in which it is necessary to develop the movements of coördination. Only slight demands must be made on the patient's strength, the periods of exercising must be short and alternated with frequent periods of rest. With these precautions it is possible by means of passive gymnastics to improve the hypertonic condition of the muscles. The movements should be executed very slowly and only sufficient force used to overcome the muscular rigidity. The smaller muscular groups in the hands and feet are first taken up and then the larger ones included. The patient is directed to relax completely, and the part not included in the movements must be supported and held at rest. As the rigidity is usually localized in the flexor muscles, passive extension must be employed to overcome the same. As soon as the rigidity disappears, the tremors are also observed to subside. In addition to these passive exercises, the author also recommends careful massage of the skin and muscles, supplemented in selected cases by more active movements. It is found that when the disease is not too far advanced, the patient can, by an effort of the will, inhibit the tremors and overcome the rigidity temporarily. There is a possibility, however, and on this the author's claims depend, to develop and perfect the power to correct these motor disturbances by strengthened cerebral impulses by means of graduated exercises, guided by the patient's mental efforts. By concentrating his mind and attention on the subject the subject is directed to control the tremor in some particular part, such as the hand, until this can be done without effort. These exercises are then extended to all parts, including correct posture of the trunk and head. In order to increase the effect on the extensor muscles, slight amounts of resistance may be interposed, preferably by means of suitable apparatus, so that the exact degree of resistance may be measured. Whenever the pulse becomes accelerated, the exercise must be stopped until the normal rate is reëstablished. Regular attempts at walking must be made also, with especial attention to the anomalies in posture of the limbs and the head. Giving a normal swing to the arm from the shoulder is usually a difficult thing to accomplish successfully, as is also the proper action of the foot. A slow heel and toe gait, with steps of varying length, must be practised, until the patient can do this without any mental effort. Attempts at walking backward and sideways should also be encouraged. The author has had some clinical experience with this method, and believes that in most cases an improvement in the motor disturbance can be brought about. The treatment should be carried out under the personal supervision of the physician and requires a great deal of patience and endurance. It should be kept up for several weeks in a systematic manner, or until definite results are evident—*Zeitschrift für diätetische und physikalische Therapie*, Vol. 7, No. 12.

THE PSYCHOLOGY OF LYNCHING.

THE practice of lynching was most justly stigmatized by the members of a religious conference recently held in this city. And it was unanimously agreed that our Federal and State governments be called upon to bring "the incitors of mobs for any cause whatever to swift and impartial justice." Such sentiments as these are certainly appropriate; but they do not go very far. No plan for the suppression of lynching will be effective that does not take into consideration fundamental human instincts. Simply to memorialize governments is not enough; for a government itself is only effective in so far as it represents the spirit of its respective community.

Almost daily the lay press describes how human beings, generally negroes, are hanged or burned. Many of these killings are attended with dreadful atrocities. Last year, in this country, 118 negroes were lynched, of whom 37 per cent. were charged (probably not all justifiably) with crime against women.

Let us note the incipiency of such lynchings. First, there was perpetrated by negroes the horrible crime against defenseless womanhood, which on the instant wrought up bodies of white men to perfectly natural frenzy. So that lynching under such circumstances might well have been condoned, even though the machinery of the law were altogether adequate for the certain and speedy punishment for such assault. In the course of time, however, these lynchings have come to be perpetrated for other, sometimes extraordinarily petty, reasons, or really, in certain cases, for practically no reason whatever. It really seems that on occasion something of the British sentiment, "It's a fine day; let's go out and kill something," has been emulated.

Down South, the crime against womanhood is now only occasionally put forth to excuse a lynching. It has from time to time been reported that not only adult negroes, but old men and boys and negro women, indeed, have been slain for the most trivial offences. A suspicion, however puerile, has in many cases served; in many no trouble has been taken to fasten an alleged crime definitely upon any one negro. And some of these killings are reported to have been done most horribly—in one case the liver of the victim having been cut into small pieces and distributed among the crowd, to be kept as souvenirs of the occasion. If we look back, from the very beginning of history, we will find it difficult, indeed, to recall any period in which the present-day barbarities perpetrated against the negro in this country have been exceeded.

Human civilization is an evolution from savagery. Slowly and painfully we have risen to our present lofty plane from the condition, æons ago, when our ancestors, in order to sustain life, had to fight other animals only a little lower in the scale of development. The civilized man of to-day represents the latest step in evolution. In him the higher brain centers—those concerned with memory, association, ideation, reason, intellect, and the like, are most developed, and it is they which ordinarily dominate his life and his conduct. Such a man has passed upward and beyond the evolutionary stages represented by the savage. The latter is practically incapable of abstract thought, in him the higher brain centers are undeveloped. His conduct is dominated by lower and more primitive centers; it is unreasoning, passionate, impulsive, imitative, and instinctive; uncontrolled emotion characterizes it.

The changes produced in an intelligent individual by hypnosis illustrate well these different states. Before hypnosis one is in full possession of all his faculties; he is "king of all that is under his own hat." But by hypnosis higher brain-centers are inhibited; they are for the time being out of the circuit. The hypnotized may then be influenced through his lower, less developed, and more primitive centers. According as the hypnotizer directs him, he expresses the basal emotions of fear, hate, rage; he exhibits the primitive instincts of cruelty and the desire to kill; he has lost all power of reason and of self-restraint.

There are certain factors in ordinary life which produce in the individual the same results as hypnotism does—such are imitation, suggestion, and the contagion inherent in social excitements. These are at the bottom of most of the crimes with which the pages of history teem—the St. Bartholomew massacre, Jew persecutions, witch killings, the French Revolution, and so on. And it is important in connection with these factors to recall *Le Bon's* dictum, that "The quality of the individual in the crowd is without importance. From the moment they are in the crowd the ignorant and the learned are equally incapable of observation."

It is thus that our fellow citizens in the South have come, in moments of excitement, to have their reasoning powers and their better sensibilities blunted. Of course to kill negroes indiscriminately is not their normal attitude; for a naturally kindlier or more humane people does not exist.

These negro murders, indeed, are not by any means confined to our Southern States. Some time ago a negro shot a policeman who tried to arrest him. His having to pay the full penalty for this deed was as absolutely certain as any human event could be. Nevertheless, that night there was a race riot. Quite harmless, industrious, law-abiding negroes were struck with deadly weapons, stamped upon; and innocent colored women returning from their work were shamefully attacked. Street cars on crowded thoroughfares

were stopped, and inoffending negro men and women were dragged from their seats over the laps of other people, and were all but murdered by brutal mobs. Next morning these whites, upon calm reflection, must have wondered how they had come to be seized with such insensate frenzy. And this happened, not in any one of our Southern States, but in New York, the city most advanced and most representative of civilization in the Western hemisphere. It has, indeed, taken many centuries for humankind to have become civilized; it is a matter of daily observation, however, that relapses to complete barbarism are practically instantaneous.

What is the remedy? Human progress has been achieved mainly through the efforts of individual men, isolated altruists, in whom the *wille zum guten*, the striving after the ideal, has risen above the merely animal will-to-live, no matter at what cost to other creations. And negro slaughter will cease only when individual men of courage and character, who are able to withstand the hypnosis that has seized upon their fellows, can influence them effectively upon altruistic and religious lines.

AS TO EATING.

It is generally believed that the ordinary individual eats more than is necessary—in fact, that the amount of food consumed is, as a rule, calculated to do more harm than good. While this belief is to some extent warranted, it has been by no means clearly proved that the majority of mankind eat to excess; indeed it is quite as likely that the reverse is the case.

A series of experiments have recently been concluded under the auspices of the Sheffield Scientific School of Yale to determine the point as to whether the average human being does not eat too much. Prof. Russell H. Chittenden, the director of the school, who conducted the experiments, read a paper on the subject before the National Academy of Sciences at Washington on April 20, in which he stated that, as a result of the investigations, the conclusion had been reached that the average healthy man eats from two to three times as much as he needs to keep him in perfect physical health and vigor. The experiments were made on three classes of men, several professors of the school, some students, and a squad of United States soldiers. In nearly all the tests, meat was gradually reduced, with little if any increase in starch and other foods. No fixed regimen was required in any case, the endeavor being to satisfy the appetite of each subject. The experiments, which lasted a period of from six months to nearly a year, ended a short time ago, when, according to Professor Chittenden, all his subjects were in the best of health. Their weight in some cases was almost exactly the same as when the experiments were begun, and in some slightly lower. Their bodily vigor was greater and their strength was much greater, partially owing to their regular physical exercises during the experiments, and partially due, Professor Chittenden believes, to the smaller amount of food eaten. The daily consumption of food at the close of the experiments was much less than the recognized standard, and from a third to a half as much as the average man eats.

It is undoubtedly true that overeating is distinctly harmful to health. Some hold that more persons are injured by overfeeding than by overindulgence in alcoholic stimulants. Further, the statement is incontrovertible that a certain class of the population of the world eat in a manner which is decidedly prejudicial to their physical and mental well-being. In the higher or richer classes such an individual is termed a gourmand, while in the more vulgar language of the working classes the gross feeder is styled a glutton. The ordinary healthy person may, also, eat in excess of his real need, and would probably do equally as well if he curbed his appetite for food within more stringently narrow limits. Such instances, however, occur mainly among those who can afford to eat whatever they may desire. Their number, however, is not so large as some would have us believe, even in these days of vaunted prosperity. Overeating is principally prevalent among that class who have the money to spend on self-indulgence and who frequently fall into the habit of literally gorging themselves. The majority of the inhabitants of the world who earn their bread by the sweat of their brow, cannot spare out of their wages sufficient to enable them to gratify their eating propensities, but are compelled to live frugally. Many of these do not consume enough nourishing food, and it would be to their physical and mental advantage if they partook of a more generous diet.

Again good cooking, suitable food, and avoidance of monotony in diet are just as important factors in the preservation of "the sound mind in the sound body" as is the quantity of food consumed. Variety is the spice of life and without the savor of change, food does not work the good expected of it. At the same time the diet should be wholesome and plain, and the canned and preserved foods, which are so prominent features in the cuisine of modern civilization, should be avoided as far as is possible. In the United States and in Great Britain the population do not require to be warned so much against the ill effects of overeating, as against nonnutritive and deleterious food and bad cooking.

The conclusions reached by Professor Chittenden are interesting, but prove nothing definitely. If he is of the opinion that the deductions to be drawn from the investigations are that the daily rations of the average person should be cut down, experience would seem to be against his point of view. Underfed nations have never been in the forefront of civilization, but have always been the easy prey of those peoples who have been able to satisfy thoroughly the cravings of their stomachs. The matter is of little concern to the average person, but touches closely the well-to-do individual.

The problem of what to eat and how to cook food is of greater moment than the question of overeating. An editorial in the *British Medical Journal* of a recent date states the situation aptly in the following words: "What to eat and what to drink will always be decided by national custom and individual preference, so far as the public is concerned, but both may be influenced in the right direction by the guidance of skilled medical opinion."

THE CONDITIONS IN BELLEVUE HOSPITAL.

The existing state of affairs in Bellevue Hospital point a moral and tend to drive home the oft-repeated truth that the city of New York needs a municipal hospital properly constructed and of a size sufficient to accommodate its indigent patients and its medical and nursing staff. Attention has been so frequently drawn to the fact, that its reiteration is almost tiresome, of the inadequacy and unfitness of the ramshackle collection of buildings known as Bellevue Hospital. But now that plans have been drawn for the construction of a new Bellevue, too much emphasis cannot be laid on the necessity of building on a large and generous scale. The plans call for an outlay of $11,000,000, an immense sum, but, when everything is taken into consideration, not an excessive one. In such a matter parsimony is out of place. The hospital as it is now is objectionable in most of its features, and injurious to health in others.

Not the least obvious fault in the construction of the present Bellevue is the lack of space for the accommodation of the resident medical staff. The sleeping quarters of the house physicians and surgeons and medical assistants is limited to an absurd degree, three and four, and even more, of these being compelled to sleep in one small room. Owing to the crowded condition of the hospital during the past few months, the physicians have been greatly overworked, in consequence of which and of the manner in which they have had to live generally, some have broken down in health under the strain. Two of the resident staff are said to be suffering from tuberculosis, a question deserving of close scrutiny in view of the different opinions regarding the infectiousness of that disease. It must, however, be borne in mind that a physician is as liable to contract the disease as a layman if he is predisposed to it and lives under conditions which tend to sap his vital powers. The doctor is not immune to tuberculosis, and the reason why he does not contract the malady so frequently as the layman is that, as a rule, he leads a healthy life, with plenty of out-of-door exercise. In the case of the Bellevue physicians, all the conditions under which they lived were of a nature to render them susceptible to disease. Through the strain of overwork they were physically and mentally run down, and in addition lived in an insanitary way. Thus the soil was ready, the seed fell upon fruitful ground, and tuberculosis was the result.

The plans for the new buildings provide for fresh air and plenty of it. Ample quarters will be prepared for 125 doctors, so that they will be not huddled together in unwholesome, ill-ventilated rooms, in which facilities for speading tuberculosis are abundant. The nurses also will be well cared for.

There can be no doubt that the public conscience has been aroused with regard to Bellevue and its allied city hospitals, and that in the course of time fine hospitals worthy of New York will be erected in their stead. This desirable consummation will not be reached for many years, and in the meantime steps should be taken at once in the behoof of the resident staff, and especially with respect to their sleeping accommodations. Temporary buildings might be erected for this purpose, or even tents would serve this object in the summer. At any rate, no efforts should be spared to remedy existing conditions.

The Cure of Insomnia.

Sir James Sawyer of Birmingham, England, in the revised edition of "Contributions to Practical Medicine," recently published, discusses this matter. He says there is no "rule of thumb" cure for this condition, but each case must be separately studied, and the details of its cure can only be decided under competent medical advice. After referring to the various hypnotic drugs used to induce sleep, the writer utters a serious warning with regard to the risks which attach to the administration of powerful hypnotic drugs. "All drugs," he says, "which produce sleep as a physiological effect, and the relief of insomnia as a therapeutic action, with the exception, perhaps, of the bromides, produce stupor rather than sleep in overdoses, which deepens into the sleep which knows no waking when they are ingested or injected in larger doses still. So never allow a patient to drug himself with hypnotics." In fact these should never be used but as temporary remedies, when it is necessary to secure at once a fair amount of sleep. Nevertheless, Sir James Sawyer is of the opinion that although change of air and surroundings will often do much to cure, yet in many cases of psychic insomnia drugs cannot be dispensed with. In such cases and in well-nourished patients, potassium bromide should be given in full doses; after getting into bed, from 30 to 60 grs., dissolved in water, should be given. When a sleepless patient is anæmic his diet should be generous, and iron and arsenic should be administered, while as a hypnotic alcohol is often useful.

Daily bodily exercise is a necessity for those who suffer from insomnia, and sunshine is a natural tonic and calmative. In order to promote the sleep of a person in bed, the bed clothing should be sufficient but not excessive. At a temperature of 44° F., the upper bed clothing should consist of a sheet, three blankets, a light counterpane, and a light small blanket; at a temperature of 70° F. it should be a sheet only. Between these extremes of temperature the changes in the thickness of the covering bed clothes should be gradual. In all cases the bedroom window should be open all night, and all the year round. In some cases the writer recommends that a little food be taken just at the time for sleeping. In the toxic kinds of insomnia, the maxim, "*Cessante causâ cessat et effectus*," must be followed. The consumption of tobacco, alcohol, tea, etc., must be stopped or lessened. The question in cases of this nature is not what the patient must do, but rather what the patient must not do.

The Army Medical Officer as a Sanitarian.

The duties of the military medical officer are various—it might almost be said multifarious. He may be termed, without much exaggeration, a medical "jack of all trades." His knowledge of medicine and surgery must be accurate and wide, and he should be acquainted with all the modern methods of his profession. The competent army medical officer must moreover possess a good knowledge of sanitary affairs. This is perhaps the most essential part of his medical mental equipment. It falls within the scope of his duties to prevent disease. In order to effect this object he must supervise to a great extent the mode of life of the soldier.

The *Journal of the British Royal Army Medical Corps* is publishing letters from the late Sir Thomas Longmore written during the Crimean War. In one of these letters he says: "There is another point of view from which the military medical officer should be regarded. He is a veritable sanitary commissioner. His province is as much to prevent disease as to cure it. He has to search out and neutralize its sources, to arrest its progress when an outbreak occurs. In civil life the surgeon or physician treats the cases in which his advice may be asked; it is the duty of others to perform the offices I have just mentioned. Soldiers require constant watching, for their own sakes as well as for that of the country at whose cost they are maintained. Few of them have the necessary knowledge or care, even of self-preservation, beyond the common animal instincts; none of them has any knowledge of the many essentials to be attended to in order to ensure a general safety when they are herded together in masses. Even intelligent military officers who have not thought on this particular subject, often hold very limited or mistaken ideas respecting it, and I believe it would be for the benefit of the medical officers if they had more direct influence than they have in matters of sanitary influence."

Although Sir Thomas Longmore wrote nearly fifty years ago, his words are almost as applicable to the state of sanitary affairs in armies to-day as in 1856.

Whenever a war is in progress its continuance is but brief ere disease breaks out, usually in the form of typhoid fever. There would seem to be no doubt that the maladies incidental to armies in the field might be prevented to a great extent by the enforcement of strict sanitary regulations. To bring this about, however, medical officers must be trained in sanitary matters, and must be allowed a freer hand than is at present the case.

Peculiar Forms of Hand Infection.

Two cases of a peculiar form of hand infection, due to an organism resembling the Koch-Weeks bacillus, have been recently reported by Dr. John R. McDill, Manila, and Dr. William B. Wherry, Bacteriologist, Biological Laboratory, Manila. The first case occurred in a hospital surgeon, who had been treating cases of acute suppurating conjunctivitis and one case of leg infection which ended in septicæmia. Soon after, a small, painful, reddish papule was noticed on the tip of the right forefinger, which gradually increased in size. The papule was twice lanced, no pus being found, but the nurse who lanced the finger on the second occasion pricked her own finger during the operation. After about five weeks of severe suffering the finger of the hospital surgeon gradually returned to its normal condition. The case, however, of the nurse was far more serious, resulting eventually in gangrene of all tissues of the finger implicated and necessitating amputation. In the remarks upon these cases the writers draw attention to the fact that surgeons treat all these inflammatory processes, usually described as panaris or panaritium, as if a disease of one causative origin, and direct all efforts to preserve the functional uses of hand and fingers. "It may be questioned," say the authors, "if this is in accord with the present state of our knowledge of these conditions; but actual results bear out the general practice in a striking way, and will continue to do so until specific agents have been produced with which one can more successfully combat the special pathogenic microbes of these inflammations."

Koch's culture experiments have shown that in every case, one kind of germ or another, or several together, can be found in the inflammatory exudate, and they are usually briefly described as pyogenic bacteria. Streptococci, staphylococci, and, in rare exceptions, bacilli such as the Proteus and Coli Communis have been found, and the clinical course of all seems much alike and to be modified similarly by the anatomical peculiarities of the part first affected. The writers state that the usual history of extension of the destructive processes along the paths of least resistance has given rise to the imperative therapeutic law—incision, disinfection, and drainage as soon as possible, and let the cuts be made too soon and too deep and long rather than too late.

Notwithstanding the difficulty experienced in obtaining the first culture, the bacillus adapted itself to a saprophytic existence and grew readily upon the "ordinary" media.

There were several cases of acute contagious conjunctivitis in the hospital at the time when the above-mentioned infections occurred. The bacilli in the cover-slip preparations from these cases corresponded in their morphology, size, and staining reactions with those in the preparations from the fingers of the hospital surgeon and nurse. They also corresponded in their morphology, distribution, and staining reactions with the descriptions of the Koch-Weeks bacillus. The authors concluded that the organism isolated from the cases described above was the Koch-Weeks bacillus itself, or a closely related "type."

Primitive Types among Italian Emigrants.

In the annual report of the Surgeon-General of the Public Health and Marine-Hospital Service for 1902, Dr. J. M. Eager discusses the types of Italian immigrants as observed at the ports of Naples and Palermo.

The writer was struck by the fact that, besides the ordinary deformities, there are also very frequently seen at the inspection many slight deviations from the normal physique, interesting in themselves, but not grave enough to warrant rejection. Among the most striking of these departures from the ordinary human type are those marks of inferiority which have been so thoroughly studied, especially in Italy, in their relation to crime. Mongolian and negroid types are common enough, and heads are often seen reminding one of those skulls of primitive man that have been found preserved in caves in France, Belgium, and England. Frequently an undersized peasant is seen with the abnormal skull, the hollow forehead, the somewhat oblique eyes, the deformed and displaced ears, the flattened nose, the great prominence in the masseteric region, the prognathism, and other stigmata so much dwelt upon by Lombroso in his anthropological studies.

Referring to the immigration laws of the United States as they bear upon this question, Dr. Eager says:

"In observing these inferior types, one is tempted to hazard a conjecture as to the usefulness of such material for the formation of the future American. It is generally admitted that primitiveness is conducive to disease. Inferior types of men are more prone than advanced types to disease when surrounded by the whirl of modern social life. Then, too, there is the question of delinquency. The view is generally accepted that men of the primitive type have a special criminal tendency, manifested particularly when they are brought into a highly organized society. . . . Under the immigration laws of the United States all persons are excluded who are likely to become public charges. It would be interesting to know

what proportion of these retarded people develop, in the land of their adoption, those latent propensities which are attributed to them in their own mind. It is taught that primitive types in Italy are on the borderland of delinquency, and that they show, among other physical defects, a jealousy for their women; a lack of confidence in the action of organized justice; a tendency to do for themselves, regardless of the common practices, customs, and laws of the country; the love of revenge, and the transmission of the vendetta from father to son. Though not necessarily effective delinquents, it seems to be admitted that these backward people possess those moral qualities that under suitable environments develop into criminality, and that their lack of physical stamina means proneness to disease."

An undesirable class of immigrant is flocking to this country Undesirable from many points of view, not only does the alien bring in dirty and contagious diseases, such as trachoma, but he is, as Dr. Eager points out, frequently defective both mentally and physically.

This is true of other immigrants besides those of Italian birth. The rush of immigration into the United States, for a variety of causes, will probably be greater this year than ever before, and it is a question if the laws regulating immigration should not be made more stringent.

A French Preventive of Race Suicide.

An institution was founded some years ago in Paris, by Drs. Budin and Variot, in the attempt to arrest the decreasing population in France. This institution is known by the name "The Drop of Milk," and is intended for the maintenance of children during the first six months of their lives, in order that they may receive the proper nourishment until they have safely passed the dangers of early infancy.

The *American Review of Reviews*, April, referring to the work of this institution, says: "The children, mostly of the laboring classes, are brought to the institution upon stated days for examination, and the mothers receive a card of admission entitling them to a certain number of bottles of sterilized milk. This is to be given at home in accordance with the directions given by the physician at the institution. In general, the infants are left with their parents, but the conditions require that the mother bring the child regularly—first, to have it weighed, that the effect of the alimentation may be ascertained; second, that the mother may take part in the school of instruction; and third, for the regular distribution of the milk. Infants of all classes, rich and poor, are admitted. There is a pay section, a reduced rate section, and a free section." Gustave Lejeal, describing the work of the institution in the *Revue Universelle*, says: "Of the 850,000 children who are born every year in Paris, at least 78,000 die before completing their first year; that is, at the rate of 16 per 100, for almost half of the total mortality of the first year occurs in the first two months It is, therefore, especially during the first two months, that the infant needs to be carefully nourished. From these figures one can judge of the important influence this "Drop of Milk" will have on future generations, and it is not an exaggeration to characterize the work of Dr. Variot as an important contribution to social progress."

The question of preventing the decreasing birth rate and the mortality among infants, is one that is greatly exercising the minds of thoughtful men in many of the European countries.

France is the most conspicuous example in the world of a steadily diminishing population, but other countries, notably Great Britain, have to deplore the fact that their population show signs of a marked decrease. The native born inhabitants of the United States do not produce children as formerly, while in the large cities of this country the infant mortality is very large. Steps have been taken in many of the centers of population here to save the lives of infants by proper care and nourishment, but much more can be done in this direction.

The Need of Covering Filter Beds.

There has been ample evidence both in Europe and on a smaller scale in this country, that the most efficient means of filtering water for domestic use, and of banishing therefrom the germs of certain diseases, is by the adoption of slow sand filters. These filters were first introduced about the year 1829, and their agency in diminishing the prevalence of typhoid fever, cholera, and other affections of a diarrhœal nature is a matter which admits of no question. Excellent, however, as are sand filters, it has been found that they will not do their work properly unless covered.

An example in point, which goes to show the relative inefficiency of uncovered filters, is that of Poughkeepsie. Typhoid fever has for the past few winters been unduly prevalent in that town. Albany, using the Hudson River water taken from a more polluted source than Poughkeepsie, had only four cases of typhoid fever reported in January, 1904, while Poughkeepsie, during the same period, had fourteen cases reported. Albany up to the time of the construction of its new covered filtered beds was notorious for the number of cases of typhoid fever which occurred there, the decrease of that disease having been remarkable since the opening of the new filter system.

The *Poughkeepsie Daily Eagle*, March 21, 1904, contained an article by Dr. Frederick J. Mann on the subject, in which the true situation at Poughkeepsie with regard to its filtration plant is stated. The opinions of Mr. Allen Hazen in support of the argument urging the need of covered filters is given. The above mentioned authority, in his book on the subject, says "that north of a line, starting on the Atlantic Coast between New York and Philadelphia and then running West and passing just a little south of Pittsburgh, covered filters are needed. Places north of this line have average January temperature below freezing." It is generally admitted that wherever a mean normal January temperature below 30° F. prevails, covers for filters are necessary, as otherwise an inferior efficiency of filtration results.

From a financial point of view the use of covered filters is an economical measure. The expense of maintenance is so considerably lessened, that the primary cost is soon saved. It is a curious circumstance that the United States, in many respects the most progressive of nations, should lag so far in the rear of European countries in all that concerns a pure water supply. One would imagine that pride alone would have sufficient influence upon municipalities to induce their members to compete with European cities in everything appertaining to the welfare of the community.

There are signs that a clearer comprehension of their duties and responsibilities is beginning to percolate through the brains of civic authorities, but this feeling must be constantly aroused, or they will again sink into the state of lethargy to which they have been so long accustomed.

Plague in South Africa.

Bubonic plague has broken out in South Africa on more than one occasion during the past few years. In Cape Town itself the efforts to extirpate the disease, which at one time threatened to assume the proportions of an epidemic, were completely successful, the only case on record, it is said, in which the malady was effectively nipped in the bud. For some considerable period, however, rumors, as to the existence of plague in various parts of South Africa, have been prevalent. Not unnaturally the authorities have done their utmost to prevent such reports from being made widely public, trusting that the spread of the disease might be checked by energetic measures. Notwithstanding these efforts, plague would seem to have gained a firm foothold in Johannisberg, and the fact has been recognized that it would be useless to further ignore its presence.

Sir Walter Foster, one of the few British medical men who are members of Parliament, recently wrote to the *London Times* with reference to the report of a commission which, during the latter part of 1903, inquired into the condition of affairs in Johannisberg. This report not only conclusively proved that plague existed in that city on a somewhat large scale, but that the type of the disease was of a particularly deadly nature. The connection of rats with plague was also shown with more or less definiteness. Rats dying and dead had been found in large numbers in different parts of the city before the malady became of frequent occurrence, but as the bacteriological examinations of some of these dead rodents exhibited no positive evidence that they had died of plague, little notice was taken of the matter.

Johannisberg is, unfortunately, a town in which the plague is apt to spread luxuriantly. In the locality in which the disease has appeared all the conditions are favorable to its dissemination. "The Coolie section consists," to use the words of a witness before the commission, of "a congeries of narrow court-yards, containing dilapidated and dirty tin huts, without adequate means of lighting or ventilation, huddled on a small area and constructed without any regard to sanitary considerations of any kind." The location is densely populated, and the witness considered its existence and continuance as fraught with the gravest danger to Johannisberg, and further stated that it surpassed all insanitary spots he had seen in his previous experience. The condition of Johannisberg appears to resemble in some features that of San Francisco. The Coolie quarter of the Transvaal city may be compared to Chinatown in San Francisco, but that the former is a more unsavory spot than the latter is undoubtedly the case. At any rate, it is a disgrace to the civilization of the United States and Great Britain that such pest holes should be allowed to remain. Both the Coolie section of Johannisberg and the Chinese quarter of San Francisco should be obliterated.

A Case of Papilloma of the Bladder Successfully Operated on, with Histological Examination.—Rosario Cascino reports a case of papilloma of the bladder in an infant of three years. The urine was interrupted at the end of urination, this being followed by the passage of a small amount of blood, and accompanied by severe pain. On passing a catheter, as it entered the bladder there was a sensation of passing some obstacle, after which the catheter passed freely into the bladder. No cystoscope could be used on account of the smallness of the urethra. An epicystotomy was done, and a small tumor was removed.—*Giornale Internazionale delle Scienze Mediche*, March 15, 1904.

News of the Week.

Civil-service Examinations for the State and County Service.—The State Civil-service Commission announces general examinations to be held May 21, 1904, including the following positions: Apothecaries in State hospitals and institutions; resident physician and superintendent of nurses at the State hospital for tuberculosis; physicians in State hospitals and institutions of both regular and homœopathic schools. Applications for these examinations must be made on or before May 7. Full particulars of the examinations and blank applications may be obtained by addressing the Chief Examiner of the Commission at Albany.

The Association of Assistant Physicians of State Hospitals held a meeting in Gallipolis, Ohio, this week. Papers were read by Dr. Geo. R. Love of Toledo and Dr. Paul W. Tappan of Dayton, Ohio.

Addition to Medical Staff of World's Fair.—Dr. A. Wall, Jr., of St. Louis was appointed a member of the medical staff of World's Fair, which now numbers four physicians besides the Medical Director Dr. L. Laidley. The corps now occupies the Emergency Hospital near the *Press* Building. The uniform will be white duck trousers and coat, the latter buttoned up close to the throat like a military tunic. A gold shield with the Exposition colors and the Red Cross will also distinguish them. The staff is now treating an average of fifty cases a day. Since the organization of the medical department a total of 5,673 cases have been treated, most of which were surgical, due to accidents on the ground.

The Unauthorized Use of a Name.—The use of the name of Dr. Willy Meyer by one of the leading drug firms to advertise one of their products has entirely anauthorized has been discontinued at the urgent suggestion of the apparent abbettor of the fraud. It is a comfort to know that sometimes an innocent medical man can protect his good name when he adopts the proper method to do so.

Experiments as to the Amount of Food Necessary to Sustain Human Life in Good Health.—The chief paper read before the National Academy of Sciences on April 20 was a description of a series of experiments recently carried out by the Sheffield Scientific School of Yale to determine whether the average human being does not eat too much. Prof. Russell H. Chittenden, the director of the school, and who read the paper, said three classes of men were experimented on—several professors at the school, several students, and a squad of United States soldiers. There was a gradual reduction of meat and other proteid foods, with little if any, increase in starch and other foods in nearly all the tests. No fixed regimen was required in any case, the endeavor being to satisfy the appetite of each subject. At the end of the experiments, which lasted for six months, all the men experimented upon were in the best of health. Their weight in some cases was almost exactly the same as when the experiments were begun, and in some slightly lower. Their bodily vigor was greater and their strength was much increased, partly owing to their regular physical exercises, and partially owing, Professor Chittenden believes, to the smaller amount of food eaten. As a result of the experiments, Professor Chittenden concludes that the ordinary individual eats far more than is required to keep him in good physical and mental health and vigor.

Dr. Conrad Gets Certificate of Reasonable Doubt. Justice Davis, in Special Term, Part I, of the Supreme Court, on April 20, granted to Dr. Edw

Conrad, who was recently convicted on a charge malpractice, and sentenced to two and a half s imprisonment, a certificate of reasonable t. The ground upon which the stay and cer- te of reasonable doubt was obtained was that d not been established by the evidence that alleged act had been actually committed by ad, and that Recorder Goff, before whom ad was tried, had expressed a doubt on the tion, and said that the point raised should be nted to the Appellate Division of the Supreme t.

mmissioner on the Health Conditions of the ma Canal Route.—Mr. Parsons, a member of Panama Commission, who has recently returned his country, speaks as follows concerning the nus of Panama: "As to the health conditions, the present death rate on the Isthmus is derably higher than the death rate in the ed States and is also considerably higher than death rate should be on the Isthmus, I am dent that, with a supply of good water furnished to Colon and Panama and with a complete m of sewers, supported by proper sanitary ations vigorously enforced, both of these cities be made healthful places of residence. At nt neither city has made any attempt to e drainage nor any system of water supply, pt such as is furnished by cesspools for the er and by cisterns or wagons bringing in water the surrounding country for the latter, steps taken before I left Panama to begin investiga- for the selection of a proper supply of water oth Colon and Panama."

vel Practical Joke.—A boy, eighteen years of named Greenberger, was charged, a few days with representing himself as a health officer, demanding to vaccinate children.

ns for New Bellevue Hospital.—The plans for new Bellevue Hospital were on exhibition at mbia University on April 21. The architects Messrs. McKim, Mead & White. The sum of oo was appropriated some time ago to pay expenses of drawing the plans. The sum of ,000 has been asked for from the Board of mate for the first pavilion; and now that the s are completed no considerable delay is cted.

dium as a Pain-killer.—Richard Guenther, the ul-General of the United States at Frankfort, many, has reported to the State Department a case of cancer of the face had been rendered less through application of radium by Dr. rier of Paris. He also states that similar results ve been obtained by other noted experts. He ys that Dr. Darier has also found quick and ain-killing effects of radium in certain diseases the eye. This doctor considers the influence of dium upon the motor nerve centers of still greater portance. In two cases of nervous spasms, hich occurred three or four times a week, weak dium preparations were applied to the temples r two or three days, when the spasms ceased. a case also of presumptive inability of motion, used by nervous debility, radium effected a mplete cure within three days—probably, how- ver, through suggestion. In acute facial paralysis entirely new origin the same doctor states that cure was effected by radium in one day.—*New York Times.*

Benefit for St. John's Hospital.—Under the auspices of the Sisters of St. Joseph, a benefit to aid St. John's Hospital, L. I., was given on the after- noon of April 21 in the Knickerbocker Theatre. The play was the "Shepherd King," and the receipts from the tickets sold by the Sisters themselves aggregated nearly $5,000.

Physician Arrested for Alleged Illegal Operation.—Coroners' Physician O'Hanlon, after performing an autopsy on the body of Loretta Young, an actress, on April 21, announced that the case called for police action. The physician who is said to have performed an operation on the deceased and the nurse were at once arrested. Coroner Scholer, at the West One Hundredth Street Station, held the physician under $5,000 bail pending the inquest, while the nurse was sent to the House of Detention as a witness.

American Climatological Association. — The twenty-first annual meeting of the association will be held in the banquet room of the Aldine hotel, Chestnut street, above Nineteenth, Philadelphia, on June 2, 3, and 4, 1904.

Medical Society of the Missouri Valley.—The spring meeting of this society was held at the Lindell Hotel, Lincoln, Neb., on March 24, Dr. A. D. Wilkinson, presiding. An interesting feature of the program was a symposium on pneumonia. The annual meeting will be held at Council Bluffs, August 25. Dr. Donald McCrae was appointed chairman of the committee on arrangements.

To Prosecute Illegal Practitioners of Medicine.—At the business meeting of the Philadelphia County Medical Society, held April 20, it was decided to raise at once a fund to be used in the prosecution of illegal practitioners of medicine. A motion was adopted also for the appointment of a committee to coöperate with the coroner, the district-attorney, and the director of public safety, in obtaining evidence against persons engaged in malpractice, and in prosecuting them.

County Medical Association.—At the regular monthly meeting of the County Medical Association of the City of New York, held at the Academy of Medicine April 18, 1904, the following officers were elected for the coming year: *President*, Dr. Francis J. Quinlan; *First Vice-President*, Dr. H. A. Dodin; *Second Vice-President*, Dr. S. B. Allen; *Secretary*, Dr. W. R. Stone; *Corresponding Secretary*, Dr. J. J. Nutt; *Treasurer*, Dr. C. E. Dennison; *Member of Executive Committee for three years*, Dr. Alexander Lambert; *Member of Nominating Committee, Fifth District Branch*, Dr. F. W. Loughran.

The Orange County Medical Society of California, on April 6, elected the following officers: *President*, Dr. Foster E. Wilson of Westminster; *Vice-President*, Dr. R. A. Cushman of Santa Ana; *Secretary*, Dr. H. S. Gordon of Santa Ana; *Treasurer*, Dr. James R. Medlock of Santa Ana

Injured in Street-car Accident.—Dr. Rosa H. Engert of Chicago was one of a large number of persons injured in a street-car accident at Santa Barbara, Cal., on April 10. She is reported to have sustained a fracture of the skull, but her recovery is considered probable.

Medical Examination of School Children.—The San Francisco Board of Health has inaugurated the systematic examination of school children. The first examination was made, on April 12, by a volunteer corps of fifty physicians.

The Tri-State Medical Society of Iowa, Illinois, and Missouri will meet in St. Louis, June 15, 16, and 17.

Reported Cure of Lepers.—Dr. Isadore Dyer, physician of the Lepers' Home of Louisiana, in a lecture delivered in New Orleans on April 23, said that there were 3,000,000 lepers in existence, or

Colonel in 1889. He was for many years medical officer to the military prison at Dublin.

Captain Henry Evered Haymes, also of the Royal Army Medical Corps, has died at the early age of thirty-two. He studied at St. Thomas' Hospital, took the London double qualification in 1896 and afterward occupied resident posts at the Royal Berkshire Hospital and the Eastern Counties Asylum. He joined the Royal Army Medical Corps in 1899, and was gazetted captain in 1902. He was wounded in Egypt while serving in the Bahr-el-Ghazal. He held the Medjidie.

THE BILL TO INCREASE THE EFFICIENCY OF THE MEDICAL DEPARTMENT OF THE ARMY.

To the Editor of the Medical Record:

Sir: The new "bill" to increase the efficiency of the Medical Department of the U. S. Army is now being earnestly pressed by the Surgeon-General, and is of the most important interest to the medical profession at large, whence the new material must come.

This "bill" is simply an act of justice, as well as the entering wedge to shelve, forever, the impossible "Contract Surgeon" system as it now exists; and to increase the Medical Corps by a trained set of surgeons, who have already served from the first call for help, and to place it in the first class as to efficiency and service.

The main feature, as restricted to a short article, consists of a positive rank as first lieutenant—longevity of service—the privilege of quarters—allowances—etc. —of the officer of the same rank in the regular corps. These features are good, but they do not go far enough. To these should be added "retirement" for long and faithful service—which is but placing it on a par with the other staff departments.

In brief, this bill for the "Medical Reserve Corps" allows for past service as a volunteer medical officer, or for service in the "reserves," and in case the medical reserve officer desires to take the examination for the regular corps, and provided he has three or more years of service, he is, if passed, made a captain at once, and not, as a former correspondent stated, have to wait for from five to eight years for a captaincy.

Better than all else this bill will do away with the impossible contract system entirely, and in its place there will be organized a commissioned force of experienced medical officers (reserve) with actual rank and its privileges, and in number no more than are now serving under the present *régime*, for the surgeon-general will not recommend any officer for appointment who has not passed a satisfactory examination, and whose services have not been of the highest character as to efficiency and professional ability.

There are several changes that would make this bill as nearly perfect as possible—one of which is the question of relative rank. The new bill states that the officer entering the "reserves" must take rank next after all other lieutenants of the line or staff. Far better would be the plan that worked so smoothly in the Volunteer Medical Corps during the campaigns in Cuba and the Philippines—that of taking rank according to date of commission—but in the bill, as it is now, those who served since the first call, would have to come in after the recent graduate, who has had no service at all.

As a class we are much pleased to see the interest taken in this bill by the different societies at large, and resolutions are looked for from the national associations urging their representatives to take this matter up with the Committee on Legislation, and the added influence of personal adherents on the floor of the House and the Senate.

We also owe much to the brilliant ex-Governor of the Philippines—now the Honorable—the Secretary of War—who has been in constant contact with the medical officers, constituting the contract surgeons of the U. S. Army in the Philippines, and who has favorably endorsed this bill on account of his personal knowledge of the difficulties under which the contract system worked.

To the present Surgeon General of the U. S. Army, for his earnest efforts in the passage of this bill, and for his sense of respect and courtesy due the contract surgeons as professional men, and universal kindness to us as a class, Surgeon General O'Reilly has earned the undying gratitude, the sincere respect, admiration, and esteem of every member of the Medical Corps, who has gone into the army as a contract surgeon, or who has served under him in the Volunteer Medical Corps.

Speaking as a member of the late Volunteer Medical Corps, and as a contract surgeon, who has the best interests of this bill at heart, and who, from personal observation, having served in both capacities, is familiar with the sacrifices made and the injustice of the present system, earnestly solicit the power and influence of your pen in securing the favorable consideration of this bill by the Senate and the House, and also to further the adoption of the "retirement" clause as well as the actual rank from the date of commission.

By so doing you would be conferring an incalculable favor to the medical men who are now serving as contract-surgeons in the U. S. Army.

Late Captain Assistant Surgeon, U. S. Vols.
Contract Surgeon, U. S. Army,
Fort McDowell, Angel Island, Cal., Depot of Recruits and Casuals.

April 15, 1904.

THE PSYCHICAL RELATIONS OF TUBERCULOSIS.

To the Editor of the Medical Record:

Sir: Some months ago when I read my paper "A Plea for Justice to the Consumptive," before the Society of Medical Jurisprudence, which paper was published in the Medical Record of January 2, 1904, I invited Dr. G. A. De Santos Saxe, the author of an article which I considered would tend to increase phthisiophobia, to be present in order to discuss my paper, and to defend, if he chose to do so, his theories. For reasons best known to himself, Dr. Saxe did not appear, but he published a lengthy letter in the Medical Record of January 23, virtually accusing me of making misrepresentations by quoting him. In the Medical Record of February 13, I replied by referring to pages and lines of his article in the *New York Medical Journal*, reiterating what he himself has said in his "Analysis of the Average Consumptive's Mental Peculiarities" (*New York Medical Journal*, p. 264, col. 1, line 13). I quoted a few more of his statements; I certainly could not quote the whole article.

Dr. Saxe was not satisfied, and in a letter which appeared in the Medical Record of March 26 he again accuses me of going to great length to extract a desired meaning out of his article. What object could I possibly have to wish to distort Dr. Saxe's meaning? I am not collecting samples of phthisiophobia, as he seems to think. My sole object was to correct the impression which I thought, and still think, his article produces, that is, that the consumptive class as a whole are more prone to selfishness and crime than others. That this could best be done by refuting his statements did not seem to me illogical. If he is not a phthisiophobe I am very glad, but in spite of the explanations of his meaning in the letter, I still think that the perusal of his article would have the tendency to increase unnecessarily the prejudice against the consumptive, and against this I reiterate my protest.

To show how well justified I was in protesting against Dr. Saxe's statements, I will reproduce here his Summary and Conclusions, as they appear at the end of his article (*New York Medical Journal*, August 6, 1903, page 265). They read as follows:

"Conclusion 1. The consumptive exhibits in the average case traits of mind and temperament that have been made use of by some of the best writers of fiction in describing the characters of tuberculous persons—traits that are well worth studying, inasmuch as they are directly connected with the disease, although not specifically characteristic of tuberculosis.

"Conclusion 2. The psychical and temperamental traits of the average consumptive have not been studied by medical men with the attention which they deserve.

"Conclusion 3. The only probable theory thus far advanced as to the causes of the mental and moral degeneration of the consumptive, leading even to criminal tendencies, is that of toxic poisoning of the central nervous system by the products of the tubercle bacillus, resulting in neurasthenia, psychastenia, hysteria, and insanity.

"Conclusion 4. The fundamental factors in the psychical make-up of the typical consumptive are the loss of self-control, the rise of brute selfishness, the increase of susceptibility to suggestion, to emotion, and to nervous irritation, and the tendency to rapid nervous and psychical fatigue.

"Conclusion 7. The criminal tendencies of consumptives have been observed with sufficient frequency to justify an investigation into the medicolegal question of restricting the responsibility of a criminal on the ground that he is tuberculous. Mental and physical degeneration, together with the tuberculous intoxication already referred to, are the chief factors in the make-up of the tuberculous criminal."

Concerning conclusion 1, I wish to say that I deny that the average case of consumption presents any particular trait of mind or of temperament. My original article showed that this view is not held by myself alone, but has been very strongly substantiated by Prof. Wm. Osler and Dr. Edw. L. Trudeau, whom I quoted.

To answer conclusion 2, I may be permitted to requote the expressions of the following three authorities:

"It is to be remembered that criminals and the insane are prone to be victims of tuberculosis, and hence someone who studied this class of people would be liable to form very unjust views about the consumptive class as a whole." PROF. EDW. G. JANEWAY.

"There is no special form of insanity due to tuberculosis. Tuberculosis is more common in the insane as a result of the lowered vital conditions than as a cause of mental disease." PROF. EDW. D. FISHER.

"In my estimation it is a great mistake to use such instances as cited by Dr. Saxe, for artificial construction of a consumptive type. There is no such thing as a specific psychopathology of tuberculosis."

DR. ARNOLD C. KLEBS.

Concerning conclusions 3 and 4 I wish to say that it is absolutely unscientific, unjust, and inhumane to speak of a "mental and moral degeneration of the consumptive," or to say that "the fundamental factors of the psychical make-up of the typical consumptive are the loss of self-control, the rise of brute selfishness, etc." In this opinion I have been upheld by Drs. Hern, M. Biggs, Sherman C. Bonney, Vincent V. Bowditch, Lawrence F. Flick, Edw. G. Janeway, Wm. Osler, and E. L. Trudeau. Those who wish to read the eloquent and forcible expressions of these gentlemen I beg to refer to my original article, which appeared in the MEDICAL RECORD of January 2, 1904.

In answer to conclusion 7 I have only this to say: Although the meaning of Dr. Saxe's Summary and Conclusions should be evident to any one who reads them carefully, in his letters in the MEDICAL RECORD of January 23 and March 26 he denies having stated that any greater tendency to crime may be noted among consumptives than among normal individuals; but if this is so why should he have raised the question at all as to the "necessity of exercising clemency in consumptive criminals"? Surely, a greater tendency to crime must be observed among consumptives in order to "justify an investigation into the medicolegal question of restricting the responsibility of a criminal on the ground that he is consumptive"? I venture to say that the 500,000 to 750,000 consumptives now living in the United States would themselves protest against being considered legally a class apart, and any attempt at restricting their responsibility would be met with a just and decided protest.

Conclusion 5 speaks of sexual functions and does not enter into the present consideration; neither does conclusion 6, which speaks of tuberculous insanity, and has been already replied to by my answer to conclusion 2.

As has been said, Dr. Saxe accuses me of having misconstrued his meaning to suit my purpose. Those who may have honored me by reading my "Plea for Justice to the Consumptive" will know my purpose. Had Dr. Saxe's article not reached the lay press with the consequent nefarious results, of which I have had ample proof, I would have ignored Dr. Saxe's article; had he assumed frankly the responsibility of his conclusions, instead of denying them, I would not have inflicted this letter upon the readers of the MEDICAL RECORD. But I believe I have written on behalf of a good cause, and in the interest of men and women who, though afflicted with a chronic and severe disease, should be considered our equals mentally and morally. S. A. KNOPF, M.D.

CONCERNING THE UNRESTRAINED USE OF THE LIBRARY OF THE NEW YORK ACADEMY OF MEDICINE BY NON-MEMBERS.

AN ANSWER TO DR. TRACY'S CLAIM.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: I am authorized to ask you to print, for the information of whom it may concern, the following communication from the Counsel of the New York Academy of Medicine, dated December 29, 1903, and April 23, 1904:

35 WALL STREET, N. Y., December 29, 1903.

John H. Huddleston, M.D., Secretary, N. Y. Academy of Medicine:

DEAR SIR: On December 28 I received your letter of the 26th instant. Prior to the act of 1896, known as the Tax Law, the Academy of Medicine claimed exemption from taxation under provision of the Revised Statutes, exempting from taxation the real and personal property of every public library.

The Tax Law repealed the provisions above referred to, but exempts from taxation the real property of every corporation *organized exclusively* for educational, scientific, literary or library purposes and *used exclusively* for carrying out thereon one or more of such purposes, and the personal property of any such corporation.

Under the Tax Law, the exemption of the Academy from taxation must rest upon proof that it is a corporation organized exclusively for scientific purposes and that its property is used exclusively for carrying out such purposes. It can no longer claim exemption upon the ground that it maintains a free public library, open at all times to the public. In its relation to the tax question, the maintenance of the library is important merely in so far as it is one of the means employed by the Academy for carrying out the scientific purposes of its corporation. The Academy was not organized for library purposes, but for the purpose of promoting the advancement of medical science by such means as to them (the incorporators and their successors) shall appear expedient and proper. It would appear that, under the Tax Law, the employment of the property of the Academy in any other means for the advancement of medical science would be as valid a ground for exemption, as the maintenance of a library, and that the library may be closed to the public, without impairment of the claim to exemption from taxation.

In answer to your letter I therefore advise you that there are no legal requirements bearing upon the number of hours which the library of the Academy of Medicine shall be kept open to the public, and that the number of hours during which it shall be kept open, has no relation to the question of the taxation of the Academy.

Yours very truly,

HOWARD VAN SINDEREN.

35 WALL STREET, N. Y., April 23, 1904.

John H. Huddleston, M.D.:

DEAR SIR: In reading over my opinion rendered under date of December 29, 1903, it seems to me to be free from ambiguity, but to prevent the possibility of misunderstanding it should be amended, if it is to be published, so that the final paragraph shall read as follows

"In answer to your letter I therefore advise you that there are no legal requirements bearing upon the number of hours which the library of the Academy of Medicine shall be kept open to the public, and that the number of hours during which it shall be kept open, has no relation to the question of the taxation of the Academy, unless the invitation to the public to use the library may properly be regarded as a means employed for the advancement of medical science. Whether such is the purpose and effect of the public use of the library is not a question of law but a question of fact, upon which I express no opinion.

"Very truly yours,

"HOWARD VAN SINDEREN."

You will notice, Mr. Editor, that the above is not controverted, but is confirmed by a correspondent who copies (page 666, of the MEDICAL RECORD) from a letter to him by "the Tax Commissioner" the following:

"In 1901 . . . at this time the commissioners made an exhaustive examination, and decided that because this property was owned by a corporation organized exclusively for the mental improvement of men and women for educational, scientific, and library purposes . . . it was still entitled to exemption."

JOHN H. HUDDLESTON, M.D.,
Secretary, The New York Academy of Medicine.

APRIL 26, 1904.

EYE-STRAIN AND EPILEPSY.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: Will you not kindly do me the favor to correct a mistake in your issue of April 16, 1904, page 629, in your review of my article published in *American Medicine* of April 5, 1904, on "The Non-operative Relief of Eye-strain for the Possible Cure of Epilepsy, as Tested in Sixty-eight Cases at the Craig Colony."

Your review makes it appear that I favor the treatment of epilepsy through the use of glasses for the correction of eye-strain. The forepart of the article in question was written by myself; the addendum by Dr. Gould.

In the review his statements are mixed with my own.

Dr. Gould believes epilepsy can be cured through the relief of eye-strain.

I do not share his views.

I have never seen such a cure. In one of the sixty-eight cases that Dr. Gould put glasses on at the Colony, the patient went fourteen months without an attack. Then they recurred as bad as ever. None of the sixty-eight cases Dr. Gould endeavored to cure with glasses were cured.

Under other forms of treatment in vogue at the Craig Colony, I have witnessed recoveries in over 5 per cent. of chronic cases. (Less than 1½ per cent. of the epileptics the Colony receives have had the disease for less than a year when they are admitted.) Practically one-half of them are beyond cure at the time of their admission.

I would esteem it a favor if you will kindly let this appear in your valuable Journal.

W. P. SPRATLING, M.D.

SONYEA, N. Y., April 18, 1904.

Progress of Medical Science.

The Boston Medical and Surgical Journal, April 24, 1904.

Some Clinical Observations on the Care of Septic Wounds.—Arthur L. Chute states that in a septic wound the organisms which are actually doing the damage are in the tissues, and the application of an antiseptic, particularly one like corrosive sublimate, which is precipitated by albuminous substances, has little chance of reaching them. Various clinical phenomena, the writer believes, give reasonable ground for doubting the penetrating power of antiseptics when applied to septic wounds. The wall surrounding a focus of suppuration becomes, as soon as it is opened, an excreting rather than an absorbing surface. Another point against the absorption, or if there is absorption, against the efficacy of antiseptics in these wounds is the fact that the signs of infection first disappear in the periphery of the red, indurated area surrounding a septic wound. If antiseptics had any considerable influence on this process, it would seem that the area nearest the wound would be the first to clear up, as it is most intimately in contact with the antiseptic. The writer has observed that septic wounds treated aseptically clear up quite as soon as when treated antiseptically. He believes that the antiseptic dressing, when applied to septic wounds, fails in the only advantage which in theory it possesses over the aseptic dressing, and that it exerts no appreciable bactericidal action. A dressing for a septic wound should secure three things: It should give protection from infection from without; it should drain the wound well; it should stimulate, as far as possible, the proliferation of healthy granulations. As far as protection is concerned, both the moist and the sterile dressing are efficient. Neither has any great advantage over the other. But the dry dressing drains the septic cavity much better than does the moist dressing. The granulations from the use of dry dressings are more healthy and vigorous than when moist dressings are used. The writer concludes that dry sterile gauze dressings are far preferable for the dressing of septic wounds for the reasons already mentioned, while moist dressings and antiseptic baths and irrigating fluids have a depressing effect on the granulations; moist dressings are, however, indicated when one cannot obtain sterile dressings or cannot depend upon the aseptic skill of the persons who are to apply the dressings. "Antiseptic poultices" are not to be preferred to sterile dressings, and there is at times a danger in their use; in case irrigating fluids are necessary, when from some unusual reason we are unable to make a wound of such shape that it can be properly dressed, sterile salt solution should be the irrigating fluid used. Peroxide of hydrogen should be avoided, since in partly closed cavities or loose tissues its gas production may make it a spreader of infection. The use of dry sterile gauze meets the indications in the routine treatment of the great majority of septic wounds better than any other material.

Journal of the American Medical Association, April 23, 1904.

The Intracellular Toxin of Bacillus Pyocyaneus.—The experiments of D. R. MacIntyre lead him to the following conclusions: (1) Bacillus pyocyaneus does contain an intracellular toxin. (2) This toxin cannot be extracted from the cell by physiologic salt solution. It is in part extracted by dilute sulphuric acid. (3) Heat to 120° C. in the autoclave continued for thirty minutes only slightly diminishes the toxicity of the cell substance. (4) The cell substance of Bacillus pyocyaneus contains a hæmolysin, which may be extracted from the cell, either in the fresh state or after treatment with alcohol and ether by physiologic salt solution. (5) The minimum lethal dose of the cellular toxin is for guinea-pigs when given intraperitoneally about one part of the cell substance to 50,000 parts of body weight. (6) when injected subcutaneously in guinea-pigs in the proportion of one part of the cell substance to 10,000 parts of body weight or less no permanent ill effect results. (7) Subcutaneous injections do not give immunity to subsequent intraperitoneal injections.

The Extraction of a Toxin from Liver Cells.—A preliminary report on this topic is made by V. C. Vaughan, J. F. Munson, and F. R. Spencer, who describe their methods of preparing the toxin. The product obtained when dissolved in water and injected intraperitoneally into guinea-pigs and rabbits, kills the animal when the proportion is one part of the extract to 500 parts of body weight. When used in smaller quantities there is more or less marked emaciation, depending on the quantity injected, from which the animal recovers very slowly. So far they have not been able to secure any marked degree of immunity by beginning with small doses and gradually increasing the quantity. After acute poisoning with the quantity above mentioned, post-mortem examination shows the liver of the dead animal to be deeply congested. The spleen is soft and mottled, with dark and pale red spots. The kidneys show no gross changes, but the adrenals are markedly congested. The gastric and mesentric vessels are greatly dilated, and there are frequently found small hemorrhagic areas under the peritoneum.

More Local and Less General Anæsthesia in Gynecologic Operations.—J. C. Webster believes that many operations on the pelvic organs, usually done under general anæsthesia, can and ought to be done under local anæsthesia. Of recent years he has extended the latter plan to even major procedures in which prolonged general anæsthesia is not advisable, *e.g.* old age, cardiac, renal, pulmonary diseases, marked anæmia, chronic wasting diseases, and sepsis. He advises the use of the Schliech solution No. 2 by the infiltration method, and adds a little formalin to lessen the risk of infection. He finds that under it various plastic operations can be done on the cervix, vagina, and vulva. After the abdomen is opened we can remove diseased tubes and ovaries, shorten the round ligaments, perform myomectomy, appendectomy, and resect the bowel. It is important that the patient should be encouraged and cheered by the operator throughout the operation. If a few drops of chloroform be sprinkled from time to time on a mask held over the patient's face a strong suggestive influence is often exerted, the patient believing that she is being deeply anæsthetized. Sometimes a patient may become so nervous and excited that her struggles make it impossible to continue the operation until general anæsthesia is induced. But even if such a course is pursued, the advantage has been obtained of reducing to a minimum the amount of chloroform or ether which is necessary.

The Dangers of Potassic Chlorate.—P. Bartholow calls attention to the dangers arising from confounding potassic chlorate with potassic chloride (KCl) and hypochlorite (KClO). The three have very different chemical properties. The explosive power of the first named is often forgotten. Internally it acts in a state of almost complete molecular integrity, as it passes practically unchanged through the body; and, judging from the way in which it develops a toxic strength, it seems likely that its molecule is endowed with an uncommon potentiality, for its pharmacodynamic effects are often irresistibly sudden and fatal. This sudden explosiveness of poisonous power is to be clearly seen in the cases in which the salt has been merely used as a gargle and has caused death. There is no doubt that it may profoundly alter the composition of the blood. What an abundant clinical experience now shows is, that this alteration of the blood may take place suddenly, and after comparatively small doses. In several instances a small dose, when taken on an empty stomach, has caused death. It shows its utmost power under these conditions, viz., in which there is no mechanical interposing agency (such as food, aqueous contents of the stomach) between the salt and the avenues into the blood. It is under these conditions, as any valid observation will show, that potassic chlorate may display a treacherous power.

Medical News, April 23, 1904.

When and How Shall We Operate for Obstructing Hypertrophy of the Prostate Gland?—Paul Thorndike emphasizes the following points: (1) The catheter has as wide a range of usefulness as it ever had, in the palliation of obstructing prostatic hypertrophy. (2) The various operative procedures at present at our command are to be resorted to, with the exception of certain small classes of cases referred to (by the author), after the catheter has ceased to palliate. The time for this operative interference is at the moment when the catheter has ceased to palliate, and not after months or years of further and unavailing struggle to make it do so. The more radical operation of enucleation, on the one hand and the Bottini operation with its various modifications on the other, are not procedures of the same kind, do not have the same object in view, and are in no sense to be weighed in the balance, the one class against the other. They should rather be contrasted, the one class as radical operations aiming at a cure, and the other as efficient palliating procedures, each having its own distinct indications for its appropriate use.

Some Features of Renal Tuberculosis.—F. Tilden Brown outlines the general symptoms of this disease. The personal history generally tends to reveal a past record of more or less ill health, although there are exceptions to this. The present complaint dates from some prolonged muscular effort where exposure to wet or cold occurred at the same time. Chilling, followed by fever, results. Frequency of micturition is then first noticed. Many cases are preceded by trauma. The urine in most cases was slightly opaque. In a few cases

severe pain in the loins and down the side, with nausea and vomiting, have been experienced. The patient is usually poorly nourished, and the color is faulty. Temperature is a degree or so above the normal. There is tenderness on one side or the other, even if the kidney is not palpable. In female cases the left organ may be the seat of the disease, yet not palpable nor so tender as the commonly prolapsed but otherwise healthy right gland. Careful examination of the urine must be made. Smegma bacilli should be excluded. After the tubercle bacilli are found, the catheterizing cystoscope is brought into use. As the bladder is hyperæsthetic in these cases, an anæsthetization with cocaine or eucaine should be employed. The writer alludes to the almost pathognomonic appearance of the ureter mouth, accompanying a renal tuberculosis on the same side. It consists of an œdematous pouting, or even prolapse of its mucous membrane with more or less erosive and hyperæmic lesion on the part of its periphery. Sometimes, however, this appearance is not present. For the majority of cases the best outlook lies in a nephrectomy. If possible, a change of air, and improved hygiene should anticipate the operation for a month or two. Nephrectomy for tuberculosis should always be done extraperitoneally.

Some External Diseases of the Eye Due to Rheumatism.—Richard Kalish believes that many affections of the eye could be aborted if the fundamental condition responsible for them were recognized in time. He considers the following diseases under the title of external diseases of the eye due to rheumatism: (1) Marginal blepharitis of the young adult; (2) recurrent hordeolum or stye; (3) recurrent chalazion; (4) circumscribed bulbar conjunctivitis; (5) limited circumscribed bulbar conjunctivitis; (6) striated keratitis. The writer declares that rheumatic marginal blepharitis is precisely that condition, the determining cause not having been recognized, which authors declare "to be more or less constant, without known cause, and with little possibility of cure." Against this dictum he enters a protest, for if optical error when present be corrected, muscular insufficiency overcome, and a thorough antirheumatic treatment, medicinal, and dietetic, be enforced, rare indeed will be the case that does not respond to treatment and terminate in recovery. An early diagnosis is most important. In the case of a recrudescence of styes, some of them the so-called "blind" styes, if the patient is fitted with proper glasses, and if local irritation from dust, and exposure to heat or cold can be eliminated, the cause is rheumatism. There is but a step between hordeolum and chalazion. When the latter becomes recurrent, it is distinctly rheumatic in type. The distinctive feature of circumscribed bulbar conjunctivitis, rheumatic in its origin, is that it is localized to the conjunctiva of the eyeball and never encroaches upon the membrane of the lid. It affects but one-half of the eyeballs, and by preference the nasal sides. It must be differentiated from scleritis. In the case of conjunctivitis, there is no special tenderness of the eyeball; there is neither elevation nor discoloration of the sclera; there are enlarged tortuous vessels, freely movable over the sclera and easily emptied on pressure. The discharge is watery, the photophobia, if present, slight, and the pain, smarting in character. There is a variety of this disease restricted to the conjunctiva directly over the insertion of one of the recti muscles, which is the limited circumscribed bulbar conjunctivitis. Striated keratitis is a rare disease which strongly resembles the striped keratitis that semi-occasionally follows cataract extraction. In the rheumatic type, the cornea assumes a grayish tint, and soon a checkerboard appearance develops. Deep corneal infiltration follows, and circumcorneal injection. The writer calls attention to the omission of these subjects from the textbooks.

New York Medical Journal, April 23, 1904.

Sclerosis and Ossification of Veins.—Carl Beck reports the case of a woman aged fifty-six years, seen in consultation, in whom the saphenous vein presented perfect osseous texture. She had suffered from varicose veins of both lower extremities for thirty years. There were frequent attacks of thrombophlebitis followed by dilatation, as well as by cicatrization, the latter causing the signs of phlebitis obliterans in various portions. There was also a large ulcer, from which profuse hemorrhage had several times taken place. On removal of the varicose areas the author found a number of thrombi in the dilated veins, which in places resembled aneurysmal sacs. The *x*-rays are of great value in the diagnosis of this condition.

The Contagiousness of Pneumonia.—R. N. Wilson reports a series of three cases occurring among college students. Two were brothers living in the same house, but not in the same room; while the third was that of a college mate who boarded with them. All were in the same room during my first visit to the subject of Case I, and the latter was waited upon for two days by his brother. In Case III the patient was simply in and out of the sick-room during the two days before the subject of Case I was transferred to the hospital, and had nothing to do with the nursing or handling of the latter. The clinical histories are summarized, and from the facts brought out the following observations are made: Simple tonsillitis, so-called, is frequently a pneumococcus infection, and such a sore throat may convey pneumonia to another. Two other cases reported bear out the theory that this disease may be conveyed by the sputum. We ought to isolate our cases of tonsillitis and pneumonia and care for them as we do for the usual contagious maladies.

The Limitations of Chemistry in Infant Feeding.—This topic is discussed by H. D. Chapin, who finds that some of the old laboratory tests for milk are not entirely reliable, and that the tests required nowadays should be based on modern chemical knowledge of the digestive peculiarities of milk. He does not disparage chemical analysis of foods, but shows that food chemistry has limitations in practical feeding. If the whole basis of the teaching of infant feeding should be chemical, then the principles taught have frequently been wrong, as it is now known that some of these principles have been erroneous. Cow's milk and human milk have been analyzed many times, but the advances in infant feeding have come, not so much from these analyses, as from clinical and physiological experiments with cow's milk, altered or modified in other ways than by simple quantitative adjustment of the component parts. The advances made have been greater along the line of physiological adaptations of various milks to the feeding requirements than from exclusive chemical studies. If chemical composition alone is to be considered, cellulose should be as good a food as starch; cane sugar, always interchangeable with milk sugar; and all caseins should act exactly alike. This we know they do not do.

The Soules Method of Burying the Stumps of the Appendix and Mesoappendix in Appendectomy.—The method is thus described by T. E. Soules: After the appendix has been brought up, the mesoappendix is tied off at or about its center in sections varying from one to four, usually two or three, according to length; each succeeding ligature being made to include some fibers of the preceding. The mesoappendix is then cut down to its base, the adherent mesentery is carefully dissected from the appendix and removed, and a circular incision made through the peritoneal envelope down to the musculoconnective tissue, at or near its tip, and carefully peeled off throughout its entire length to, or very near, its colonic junction, where a fine silk ligature is thrown around the denuded base of the appendix. Another ligature is applied about one-quarter of an inch externally to this, and the cut made between the two; the appendix is then removed. The glove finger of peritoneum is then turned back again and slit along the line of former mesenteric attachment, and spread out, making a flat membrane equal in extent to the circumference and length of the excised appendix; this is then made to cover the appendicular stump, together with the bare ends of the mesocæcal stumps; and with edges turned in, if great delicacy is desired, it is carefully stitched to either side, where the peritoneum shades away over the mesoileum.

American Medicine. April 23, 1904.

Personal Observations on the Advantages of Certain Arctic Localities in the Treatment of Tuberculosis.—Frederick Sohon gives the following recapitulation: Constant sunshine, which brings health and energy, a germless and dustless air that gives neither irritation nor extra infection; an unvarying and bracing temperature that invites outdoor life and exercise; a climate that creates an appetite and a life that brings the ability to digest and assimilate; a life of new recreations that banish loneliness, and of enticing interests so different from the ordinary, that absolute nerve rest is secured; a country in which colds and catarrhal conditions are not found, and even the healthy invariably improve in well-being; all of these advantages, except the perpetual sunshine and the germless air, can be obtained elsewhere, but in the Arctic regions they are furnished altogether and each in perfection. They are also furnished at that time of the year when conditions are most unfavorable elsewhere. Three months under such conditions may be time enough for a cure in patients not greatly run down.

Summary of an Experimental Research into Digitalis in Shock and Collapse, with Illustrative Protocols.—G. W. Crile reports that in animals reduced to varying degrees of

surgical shock, digitalis usually caused a rise in the blood-pressure. When overstimulation was obtained by administering too large a single dose, or by repeating smaller doses, the heart became extremely irregular or the animal died suddenly from cardiac failure. In some instances convulsions occurred. The respiration, when at all affected, was either impaired or arrested. Death in the digitalis experiments was usually more sudden than in the controls. It seemed, on the average, that in cases of shock the animal treated by digitalis did not live so long as the controls. In the experiments in which the medulla was cocainized, and those in which the cord was severed just below the medulla, digitalis caused a distinct rise in the blood-pressure. When the heart had ceased to beat, digitalis introduced by intravenous infusion or by direct injection into the chambers or the walls of the heart did not produce any appreciable effect. The animals showed considerable idiosyncrasy in their reaction to digitalis.

The Importance of Considering the Element of Vasomotor Instability in Estimating the Significance of Irregularity of Cardiac Rhythm.—Louis Faugeres Bishop states that the vasomotor system is far more liable to disorder than the heart, and the heart is able to compensate for a good deal of misbehavior on the part of the vessels, but in compensating it often appears to be misbehaving itself. So one may fall into the error of predicating disease of the heart-muscle when the trouble really is a functional derangement of the blood-vessels. Diseases of this class, including myocarditis and nephritis, have their origin most often in degeneration of the blood-vessels, at first functional, and then organic. The coronary arteries of the heart become involved and then the heart-muscle suffers. The vasavasorum of the blood-vessels are affected and then the larger vessels. The writer concludes that, thus, even in the first stages of circulatory symptoms, the relationships should be appreciated, and the hygiene of the peripheral circulation becomes a matter of serious supervision.

The Lancet, April 16, 1904.

The Treatment of Cancer with Radium Bromide. —H. G. Plimmer tabulates the results in seventeen cases, many of which were in an advanced condition. The diagnosis was confirmed in all of them either by the examination of the primary growth or by the excision of a nodule. The individual exposures varied from forty minutes to five minutes; and the capsule containing the radium was placed directly on the nodules or lumps, the only thing intervening between the radium and the skin being the talc top of the capsule. The cases were left for a month after the exposures and then examined to see in what condition they were. The effects in all the cases were negative, either no changes or an increase in the size of the nodules. The effect on the skin varied in the different cases; an exposure of ten minutes was generally sufficient to produce blistering, and under the scabs there was found a very slowly-healing ulcerated surface. The radium had no apparent effect with regard to either causing or relieving the pain.

Notes on a Case of Myelopathic Albumosuria.—The patient of R. C. Bruce, K. F. Lund, and P. P. Whitcombe was a woman of fifty-one years, who presented the usual symptoms which have been recorded in this rare affection, viz., (1) The fragility of the bones. (2) The extreme anæmia and lassitude. (3) The pains of neuralgic character, varying in intensity and situation, aggravated by movement, and accompanied by local tenderness. (4) The presence of a semi-fluctuating tumor over the acromial end of the clavicle in connection with the false joint. The peculiarities of the case were: (1) The fractures occurring solely on the left side. (2) The occurrence of the disease in the long bones, humerus and femur; no disease in cranial bones. (3) The absence of any prominences on the bones. (4) The sharp grating crepitus of the fractures resembling that produced by old dried museum specimens. (5) The fact that a firm union took place in one of the fractured bones, viz., the femur, although infiltrated with disease of a malignant nature. (6) The sex of the patient. Most recorded cases have been in males.

A Chronic Neurosis Characterized by Frequent Paroxysms of Pain, Swelling, and Hemorrhage in Various Parts of the Body; Death from Acute Pulmonary Tuberculosis. —The general nature of the case reported by T. K. Monro and A. N. McGregor is fully stated in the title. Their patient was a man of twenty-eight years. The areas affected were successively the knees, calves, thighs, forearms, and upper arms. The lesions often affected the limbs of both sides, but were not always strictly symmetrical. The whole period covered by the attacks was some eighteen months, but the patient finally succumbed to pulmonary disease. The general nature of the local lesions suggested that they were allied to angioneurotic œdema with certain resemblances to a disease whi is as likely as not of infectious origin—namely, the pu puric type of erythema. In rare cases of tabes dorsal small or even considerable subcutaneous hemorrhag may follow paroxysms of lightning pains, so that hemo rhage may certainly be due to nervous disturbanc Moreover, in urticaria, into which the neurotic eleme enters largely, there may be exudation not only of seru but also of corpuscles. It is to be noted that this patie was the subject of factitious urticaria. During i numerous remedies were employed for the cure or reli of the disease or its most urgent symptoms, but none them exerted any very noticeable influence. Counte irritation, in the form of a seton at the back of the nec appeared to do almost as much good as any intern remedy.

British Medical Journal, April 16, 1904.

Two Cases of Primary Malignant Disease of the Pancre —Joseph Stewart reports two cases of primary malign disease of the pancreas. He declares that in gene there should be no difficulty in the diagnosis of pancre titis—the painless jaundice, the intense weakness, gre wasting, and the enormous evacuations being charact istic. In his second case, autopsy showed the absence the gall-bladder. This condition had made the diagno difficult. There was no sugar nor albumin in the uri of the patients at any time during the illness. Anoth interesting point is that there was no constipation.

An Inquiry into the Primary Seat of Infection in 500 Cases of Death from Tuberculosis.—J. Odery Symes and Theodore Fisher conclude that: if local foci of disease are taken as evidence of primary disease in the neighborhood of the foci, the authors' statistics tend to show that during the first twelve years of life tuberculous infection by the air passages is four times as common as by the alimentary canal. These statistics also seem to show that the comparative frequency of infection through the alimentary canal during the second twelve years is equally common. Deaths in hospitals above the age of twelve years can hardly, however, be taken to represent the average causation of death from varieties of tuberculosis for the whole population above that age, because cases of tuberculosis of the lungs are more chronic than at an earlier period of life, and are not usually admitted to ordinary hospitals. in spite of the exclusion of chronic pulmonary troubles from hospitals, the proportion of abdominal to thoracic tuberculosis in the institutions from which the reports were taken was very small after the age of twenty-four.

The Glycogen Reaction in Blood; Its Pathological and Diagnostic Import.—G. Lovell Gulland, after describing the glycogen reaction, enumerates the general conditions in which the intracellular reaction occurs, as follows: Severe disturbances of respiration; anæmia; toxæmia of metabolic origin; suppuration and bacterial infection. Clinically, the chief conditions in which a positive reaction is constant, are: croupous pneumonia, bronchopneumonia, empyæma, abscess, and gangrene of the lungs, septicæmias, and pyæmias of all kinds, all advancing suppurative processes, septic gangrene of all kinds, appendicitis, and peritonitis. Some of the conditions in which the reaction is uniformly absent, are: Rheumatic fever, chorea, rickets, heart disease (unless compensation has failed badly), catarrhal jaundice, uncomplicated tubercle of all kinds, asthma, alcoholism, early cancer, lead colic, and diabetes (except when coma has occurred). This reaction is probably associated in some way with the resistance of the organism to poisons, and especially to those which produce positive chemotaxis. Many of the causes which produce the reaction also cause leucocytosis, but there is no necessary connection between the two. Patients who show this reaction are always "sick." Although the method is simple, it demands care and accurate observation.

Deutsche medizinische Wochenschrift, March 31, 1904.

The Occurrence of Free Amino-Acids in the Blood in Acute Yellow Atrophy of the Liver.—Neuberg and Richter report the results of an analysis made on the blood of a patient with acute yellow atrophy of the liver. The disease arose in connection with a recent syphilitic infection, and the clinical picture was the usual one. Both leucin and tyrosin were present in the urine though not in large amounts. By a complicated series of precipitations and recrystallizations the following amounts were recovered from 345 c.c. of blood obtained during life: Tyrosin, 0.787 gm.; leucin, 1.102 gm.; lysin, 0.240 gm., or a total of 2.13 gm. of amino-acids. Assuming that the total amount of the patient's blood was 4-5 kilog. this would give the surprisingly large quantity of 30 gm. of amino-acids free in the circulating blood. The authors are unable to draw definite conclusions as to the origin of these bodies, but consider muscular degeneration, and the intestine as the two most likely sources.

The Biology of Tumors.—Saul describes culture experiments made on tumors by means of which he was able to discover protozoon-like organisms in both benign and malignant growths. Portions from the center and the periphery of the tumors were cut into small cubes, and as soon as possible after their removal from the body were placed in test tubes containing agar and bouillon. In all cases in which it had been possible to secure sterility of the bits of tissue certain hyaline bodies were observed to develop in between the tissue cells, and with time what appeared to be various phases of development were seen. These bodies were present both in malignant and non-malignant tumors. All attempts to fix or stain them so as to make their demonstration in tissue sections possible were unsuccessful. The author concludes that the bodies described as cancer parasites by many writers are histological elements of the tumors themselves, since apparently such organisms are incapable of withstanding the methods of fixation, etc., employed.

A New Method of Approaching the Posterior Surface of the Right Lobe of the Liver.—Israel was confronted by the problem of making an exploratory incision in order to determine the nature of a disease process affecting either the kidney, adrenal, or posterior portion of the light lobe of the liver. The kidney was freely exposed by an incision beginning at the twelfth rib and running obliquely downward and forward. Both kidney and adrenal were found healthy, and the liver was then made accessible by resecting a large portion of the twelfth rib and then splitting and reflecting the renal capsule. The vessels at the hilum were freed, and the entire organ thus mobilized sufficiently to permit it to be dislocated downward and forward, as is the case with a floating kidney. The peritoneum over the posterior surface of the liver was rough and infiltrated, and further investigation showed the presence of a dense fibrous growth the size of a walnut. This was successfully extirpated without undue hemorrhage and the cavity packed. The kidney was fixed in place by appropriate sutures, and the incision closed except for the opening left for the drainage gauze. Prompt recovery followed and the patient was enabled to resume his duties as army officer. The growth proved to be a gumma.

Berliner klinische Wochenschrift, April 4, 1904.

Late Liver Abscesses Following Tropical Dysentery.—Pel reports three cases in which abscess of the liver first gave symptoms many years after the patients had returned from the tropics. In the one case no symptoms of abscess were observed until eleven years after an attack of tropical dysentery and in another not until fifteen years after a similar attack. This case is particularly unusual in that the temperature remained subnormal until the pus was evacuated, when it rose to normal and remained so. The third patient did not suffer from his abscess until twenty-one years after a long drawn-out attack of dysentery. In all three cases the pus was sterile. The author proposes to call such cases late liver abscesses.

Therapeutic Attempts with Dyes in Trypanosomiasis.—Ehrlich and Shiga publish the results of an investigation on the cure of trypanosome infections which are of especial interest, since they show the possibility of producing active immunity through the administration of drugs. The trypanosome experimented with was that producing the South American *mal-de-caderas*, and mice were used as test animals. After some experimentation a member of the benzo-purpurin group was found which was hostile to the organism. When injected into mice infected with the trypanosomes this substance, to which the name of trypan-red was given, proved capable of saving the life of the animal even if not administered until the day preceding the death of control animals. The organisms appeared to vanish from the blood, but in many instances relapses occurred. The effect of the remedy was equally certain if administered by mouth. Other animals, such as rats, could not be saved with the same certainty as mice, and relapses were more frequent, while with dogs and guinea-pigs the results were still less encouraging. The trypanosome causing *nagana* was also tested but was found more refractory to the action of the agent than that of the *mal-de-caderas*. On adding the trypan-red even in ½ per cent. solution to cultures of the trypanosome *in vitro* the latter did not perish, showing that the action of the substance is not that of an ordinary antiseptic, and it was found on injecting it into healthy mice that protection against subsequent infection lasted only two days, although the tissues remained colored for a much longer period. On the other hand, infected animals cured by the trypan-red showed greatly protracted resistance to subsequent infection. It appears therefore that a true active immunity is induced by the injection of a purely chemical agent. Many other dyes and other bodies were tested, but none showed similar action.

Münchener medizinische Wochenschrift, April 5, 1904.

Amputation of the Tonsils with the Cold Snare.—Henrici considers that serious sources of inconvenience are inherent in all the customary methods of tonsillotomy and advises a return to the cold-wire loop. Amputation with the bistoury is always difficult and with children is usually impossible. Both the guillotine and the tonsillotome of Blake are open to objection owing to the necessity of having several sizes of the instrument, and of keeping the blades sharp, there is danger of the blade of the guillotine breaking against a tonsillolith, too much of the tonsil may be cut away and hemorrhage result, etc. The galvanic snare is too unreliable and painful and involves slow healing. The cold snare is easily applied, is small and easy to manipulate within the mouth, it does not induce bleeding, one instrument does for all cases, it can be used with equal ease on either side of the mouth and the author considers it the ideal instrument.

The Theory of Sensibilitization and Observations on Some Sensibilitizers.—Halberstaedter says that in photochemical parlance optical sensibilitizers are agents that have the power of making silver salts sensitive to the rays at the red end of the spectrum, by which under ordinary circumstances they are not affected. Certain bodies have similar properties in regard to the action of light on living cells, and Dryeer has shown that erythrosin can sensibilitize infusoria, animal tissues, etc., for the usually inactive yellow-orange and orange-green rays. The importance of this observation for light treatment becomes evident when one considers that the blue rays have very little and that the red rays have much penetrating power. Eosin has very marked sensibilitizing powers, especially for the yellow and yellow-green rays, but its activity is only about one-fourth that of erythrosin. Chinolin red is an excellent photographic sensibilitizer for yellow and yellow-green and has a similar property for animal tissues, though its power is less than that of eosin or erythrosin. Cyanin has slight sensibilitizing power but is too toxic for practical application. Alizarin-blue sulphide which photographically is a good sensibilitizer for red was found inactive for animal tissues.

Spinal Anæsthesia.—Bier and Donitz say that the method of spinal anæsthesia advocated by Bier was at once taken up with much greater enthusiasm by others than was accorded it by the originator himself. Subsequent results showed that this conservatism was justified, and that in its old form the method was adapted to serve only in exceptional cases. Further observation has led the authors to conclude that the dangers of the procedure can be completely obviated by combining the adrenalin with the cocaine. The latter agent has been found more satisfactory than any of the substitutes that have been proposed and is therefore retained. The method employed is as follows: The patient lies on a table with the upper shoulders somewhat elevated, so that the back is arched from before backward and at the same time the spinal column is curved laterally with the concavity looking upward. The line joining the crests of the ilia is drawn and indicates the spinous process of the fourth lumbar vertebræ. The finger is passed upward so that it reaches the space between the second and third vertebræ, and the needle is plunged into this space instead of into that between the third and fourth, as was the old technique. As soon as cerebrospinal fluid escapes, 1 cm. of a 1-2000 solution of adrenalin is injected. The syringe is allowed to remain in place to prevent the escape of cerebrospinal fluid, and at the end of five minutes a solution containing from 0.005 to 0.02 gm. of cocaine is injected through a second syringe. Physiological salt solution is used as a solvent, as apparently it is of no advantage to employ solutions isotonic with the cerebrospinal fluid. Suprarenin was used in a somewhat larger number of cases than adrenalin and seemed slightly more satisfactory. In all 121 cases were anæsthetized in this way for operations of all degrees of severity. In none was the slightest evidence of danger observed, and the authors considered that the method in this form may be considered perfectly safe. On the other hand the headache, nausea, etc., which were such drawbacks to the old method, have not been greatly reduced and the procedure, therefore, must still remain one to be reserved for selected cases. A precaution that is advised is to assist the action of the adrenalin in preventing the cocaine from traveling too far up the cord by keeping the patient's shoulders elevated throughout the operation and never employing the Trendelenburg position.

Society Reports.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held February 29, 1904.

WENDELL C. PHILLIPS, M.D., PRESIDENT.

Some Observations on the Surgery of the Common Duct of the Liver.—Dr. WM. J. MAYO of Rochester, Minn., read this paper. (See page 681.)

Dr. ROBERT F. WEIR was greatly surprised that one man should have had so many common duct operations in one year as Dr. Mayo had and complimented him upon studying his cases so well and giving such results as were contained in the able paper. It was well worth knowing that the common duct could be investigated by passing the finger in from below upward but not from above downward, and that one need not hesitate to entirely open the common duct and explore for stones. This could be done and the common duct closed and regain its serviceableness. Regarding the removal of the gall-bladder he said that if it was needed for drainage, save it; but if it was not needed and if it could not be restored to its normal condition, it then should be sacrificed. No rule could be given but one must individualize.

Dr. ARPAD G. GERSTER was thankful for the excellent teaching that it had been his pleasure to receive from the paper.

Dr. JOSEPH A. BLAKE referred to a method of reaching the common duct by liberating the duodenum for the purpose of attaching it to the cardiac portion of the stomach by incising the peritoneum between the duodenum and kidney. In this way the duodenum could be readily turned to the left and the common duct not only palpated but inspected.

Dr. WILLY MEYER said it was sometimes very difficult for physicians or surgeons to refuse to yield to the importunities of patients who have suffered for years with recurrent attacks of colic, with stone in the common duct, when jaundice sets in for the first time. In such cases he believed it to be wise to refuse operation, for if one operated at such a time it would be similar to operating during an acute attack of appendicitis when it would be better possibly to await the interval. When jaundice supervened, he said the conditions in the common duct were then more active than at other times, and one had better wait. Many of the cases of stone existing for a long time in the common duct he said had given symptoms which were often mistaken for malarial fever, on account of the chills and fever. He emphasized the importance of an early recognition of stone in the gall-bladder and before cholangitis had existed for any length of time. Knowing that stones in the gall-bladder may be productive of stones in the common duct meant that one should be timely in operating upon the stones in the gall-bladder.

Dr. SAMUEL LLOYD emphasized the importance of preserving the gall-bladder whenever possible, particularly at this time when so many surgeons were advocating its removal in all cases of stones.

Dr. THOMAS H. MANLEY said that the surgery of the gall-bladder and ducts had been kept back for years because of the fears entertained by many surgeons of opening the upper right quadrant of the abdomen. Yet gall-bladder surgery he believed to be safer than the surgery of the appendix.

Dr. MAYO agreed that one should wait until the fever and initial symptoms had subsided in the acute cases. If there were no chills or fever and the patient did not feel very ill, one should operate at once. In acute cases, with symptoms of cholangitis, he said it was not the question of stones but the infective inflammation of the ducts that should be considered, for many cases die from such an infection without operation. He did not advocate removal of the gall-bladder unless positively indicated. The so-called ideal operation was to open the gall-bladder, remove the stones and sew it up again. The question of its removal depended upon the amount of infection. If there was no inflammation, and the stones were easy to get out, he did not see why the gall-bladder should be removed.

Special Report of the Counsel of the Society.—Mr. CHAMPE S. ANDREWS said that during the last three or four months the legal department of the society had been called upon to do more work than ever. It had to do with the men Blinn and Conrad, regarding whom the papers had devoted much space. During the last four years the complaints had so increased against these men that now they could no longer be ignored. He said it was impossible to catch such people without fixing some trap for them, as had been done in the Conrad case. He had received as many as 150 letters from the victims of these men offering to assist in the prosecution of them. Blinn had skipped his bond and Conrad was in jail trying to raise a $10,000 bail.

Ratification of the Action of the Medical Society of the State of New York to the Amalgamation of the Medical Society of the State of New York and the New York State Medical Association.—This occurred without a dissenting voice. After twenty-two years of discord peace was declared.

Stated Meeting, Held March 28, 1904.

DR. WENDELL C. PHILLIPS, CHAIRMAN.

Clinical Manifestations of Uric Acid.—Dr. EGBERT LE FEVRE read this paper. (See page 687.)

Volumetric Determination of Uric Acid and the Purin Bases in Urine.—Drs. J. RUDISCH and F. KLEEBERG considered this part of the topic. This rapid and accurate method depended upon the following principle: both uric acid and the purin bases were completely precipitated by a weak ammoniacal solution of silver containing ammonium chloride. On the other hand, in a strong ammoniacal solution, the purin bases remained completely in solution, whilst the uric acid was completely precipitated. Silver and uric acid formed a compound in which to each molecule of uric acid there was one atom of silver. With the purin bases the silver formed compounds in which the proportion was as two to one. A definite quantity of the silver solution was added to the solution to be analyzed, and the excess titrated directly to the ammoniacal solution by means of standard potassium iodide. A mixture of dilute nitrous acid and starch was used for determining the end point. Requirements: (1) $\frac{N}{50}$ silver solution; (2) $\frac{N}{50}$ potassium iodide solution; (3) a nitrous-sulphurous solution; (4) ammonium hydrate, specific gravity, 0.90.

TO DETERMINE THE URIC ACID.—The method was carried out as follows: To 110 c.c. of urine add 55 c.c., $\frac{N}{10}$ silver solution and dilute with NH_4OH, specific gravity 0.90 to 220 c.c. All these measurements could be made conveniently in flasks of the Gile's pattern. Mix and filter either at once or after standing a few minutes through a dry folded filter. Two portions of 100 c.c., each corresponding to 50 c.c. of urine, are collected. In the meantime a half a dozen small test tubes (about 8 cm. long and 1 cm. in diameter) were filled for about 1 cm. with a mixture of roughly, two parts of the nitrous sulphuric acid and one part starch. To one of the above portions of 100 c.c., $\frac{N}{50}$ KI was rapidly added and, after such addition of 2 c.c., a small portion, not exceeding 0.5 c.c., was removed by means of a pipette, which also aided as a stirring rod, and carefully introduced down the side of one of the test-tubes, in such a manner that two distinct layers were formed. The end reaction manifested itself sharply by the formation of a blue ring at the point of juncture. Having now determined the end point approximately with the first 100 c.c., the exact end point was determined with the second 100 c.c., *e.g.* say that more than 100 c.c. and less than 12 c.c. were required with the first 100 c.c. The second 100 c.c. were then taken, and 10 c.c. $\frac{N}{50}$ KI run into the solution at once. Then carefully a few drops were added

time until the exact end point was reached. Each $\frac{N}{10}$ silver solution equalled .00336 gr. uric acid. aid the entire process need not require more than ty to twenty-five minutes.

DETERMINE THE PURIN BASES.—Exactly the same ss was carried out except that instead of adding g ammonia he diluted with water, *i.e.* take 100 c.c., 5 c.c. $\frac{N}{10}$ silver, and dilute with water to 220 c.c., proceed as before. The number of c.c. of $\frac{N}{10}$ silver equalled the total purin bodies, and subtracting umber of c.c. of $\frac{N}{10}$ silver required in the uric- determination, the difference equaled the purin , bearing in mind that each c.c. $\frac{N}{10}$ silver equalled 2 gr. purin base calculated as xanthine.

e accuracy of this method was proven by estab- g the following points experimentally: (1) That ilver compound which uric acid formed under the tions stated was insoluble both in dilute NH_4OH n string NH_4OH. (2) That the silver compounds the purin bases formed were insoluble in weak OH and soluble in strong NH_4OH. (3) That known nts of uric acid when added to either water alone urine can be accurately determined. (4) That the cid determinations agreed with the determinations by the Ludwig-Salkowski method. (5) That the mination of the total purin bodies agreed with the s obtained by Arnstein's modification of Camerer's od. (6) That silver can be determined with great cy by means of KI in an ammoniacal solution.

e method as proposed deserved the designation of a cal method" in the sense that it placed at the dis- of the clinicians an accurate method for the deter- ion of both the total purin bodies and the uric acid, ermination which could be made in a short period e, far shorter than by any of the numerous other ods that had been proposed. On the other hand erm "clinical method" was looked upon by chemists ithout good reason, as a term indicating a method y inaccurate and, in this sense, the method did not ve to be known as a clinical method.

monstration of Method.—Dr. F. KLEEBERG demon- d the method as described by Dr. Rudisch.

Pathological Increase of Uric Acid.—Dr. E. E. took up this part of the topic under discussion. aid that one constant manifestation of states in uric acid was pathologically increased was *exhaus-* The products of destructive metabolism differed g the condition of over-fatigue from the normal. ver-fatigue there was an increase in the amount of acid and the action of the fatigue products was upon ntral nervous system as well as upon the over-tired es. Experimentally it had been shown that the duction of lactic acid into the body led to an increase e uric acid output, this increase being due to uric formation by synthesis through the combining of the acid with urea. It was his conviction that the e of the increase of uric acid output in disease was, any instances, what might be tentatively called rmal fatigue products of metabolism. He said that nged muscular exercise did not produce an increased ation of uric acid when the subject was in proper cal condition, but only when he was in poor physical tion. He had observed that it was not the absolute nt of alcohol that determined the increase of uric d, but the physiological effects. Thus, in an individual king alcohol in the form of whiskey there were no notice- le subjective symptoms and no pathological uric acid crease, while the same individual, at another time, king the same quantity of alcohol in the form of cham- gne, showed a distinct subjective effect with a marked thological uric acid increase. In various diseases with normal fatigue type of condition on the one hand and here there was a pathological uric acid increase on the her the clinical manifestations might be profitably udied. Thus, in fevers, neurasthenia, migraine, and the convulsive state of epileptic seizures such a relation might exist. He did not maintain that the products of over-fatigue were the only substances that gave rise to synthetic uric acid formation. It seemed probable that products formed by fermentative changes in food in alimentation might also give rise to uric acid by synthesis, thus giving rise to a pathological uric acid increase. He wished to be understood as maintaining that while it had been amply demonstrated that while the endogenous uric acid excreted under ordinary conditions of health, and which might be designated as the physiological uric acid, was almost wholly derived from nuclein breakdown in destructive metabolism, it had not been demonstrated that the uric acid constituting a pathological increase was from this source, and that the consideration of clinical and experimental data indicated that the pathological increase in many instances was largely derived from synthetic uric acid formation from other pathological products in the body.

Treatment of the Gouty Diathesis.—Dr. THOMAS E. SATTERTHWAITE considered this part of the topic. The treatment of gout varied according to the form: *i.e.* whether it was (1) Acute, of which podagra was the best example; (2) Chronic, characterized by chalky deposits; (3) Retrocedent, or, perhaps, better called aberrant, gout, where the type deviates from the characteristic variety; (4) Irregular, or minor gout, with its protean manifestations.

ACUTE GOUT.—The inflamed part should be elevated and protected against weight of bed-clothes by a cradle. Lead and opium wash made a good local application, applied on absorbent cotton, covered with oil silk, and renewed every four hours. Or, a saturated solution of bicarbonate of soda. Or,

℞ Guaiacol. . . . . .
Oil of wintergreen. . . . . āā ℥ss.
Olive oil . . . . . ℥ij.
M. Sig.

A more elegant mixture he believed to be:

℞ Menthol . . . . . ℥j.
Alcohol. . . . . ℥iv.
Glycerin . . . . . ℥j.
Cherry-laural water. . . . . ℥j.
M. Sig.

During this stage the patient may be placed in a tub at 98° to 100° F., kept there for fifteen minutes, then douched with water at 102° F. for another fifteen minutes. Afterward the flabby parts are massaged while the inflamed parts are untouched. This was followed by a mercurial purge and, later, a saline cathartic. The salicylates of lithia, or colchicum, or the iodide of potassium or sodium were used until the subacute stage had been reached, when they were abandoned for dietetics, hygienic and balneo-therapeutic measures.

As soon as possible, the wine of colchicum should be given in from 15 to 30 minims every four hours, alternating with salicylic acid, or the salicylate of sodium, at intervals of four hours. The administration of colchicum should be carefully watched and its dose lessened as soon as possible, because of the disturbance of the gastrointestinal tract which follows large dosage or prolonged use of it. He gave colchicum combined with nitroglycerin, which dilated the blood-vessels, while it acted as a cardiac stimulant. If the salicylates were not well borne he gave citrate of potassium in 30 to 60-grain doses, every four hours. One should lose no time in giving a mercurial purge; it relieved portal congestion and tended to eliminate the purin bodies. Following the mercurial purge a chologogue should be effective, and his favorite was:

℞ Resin podophyllin. . . . . gr. ss.
Ext. colocynth. . . . . gr. ij.
Ext. hyoscyami. . . . . gr. j.
Ext. nucis vomicæ. . . . . gr. .
M. et ft. pil. No. 1. Sig. One at night, if necessary.

For drinking purposes he used the waters containing carbonate of soda, of lime, of potash and lithia. During this stage the diet should be such as to meet in the fullest

manner the dangers of faulty metabolism, while the kidneys should be guarded from irritating substances. With the exception of toast and butter, the diet should be a liquid one. When the subacute stage was reached a soft-boiled egg and a weak meat or vegetable broth may be allowed.

SUBACUTE AND CHRONIC GOUT.—Here one must always bear in mind that there is an excessive formation of the purin bodies, or its allies in the uric acid group, and they must, in a measure, be met with by drugs, hot air, hydrotherapeutics, massage, suitable exercises, and diet. One should always be ready with colchicum and the salicylates or alkaline carbonates to abort an attack. He always insisted that patients should have one or two free evacuations each day.

RETROCEDENT OR ABERRANT GOUT.—In the treatment of this form he saw no reason why one should endeavor to lure away the attack from its new site to its former one. Once the deposit of this insoluble bi-urate was fixed in the joints, it was rare that it left them. He next considered the question of dietary, and said that many of the present ones had been tried and found to be useless. The patient tried them one after another, and only found in the end that he did better on a dietary of food and drink that he had found to be suitable by personal experience.

IRREGULAR OR MINOR GOUT.—In this form he said it was not necessary to observe the strict rules as in acute gout, or even in the chronic form. Yet the treatment was based on the same general principles. People afflicted with these symptoms present indigestion, nervous irritability, headaches, neuralgias, parasthesias, depression of spirits, hebetude, perhaps with the slow pulse of arteriosclerosis. The urine contained, as a rule, uric acid in excess, though the oxalate of lime might replace it. This was gout without the major joint symptoms. Here the diet should consist of the free use of water, not necessarily an alkaline water. Vegetables should be taken freely. Carbohydrates should be taken in small quantities, because they give rise to fermentation, which was active in the gouty.

He believed the following conclusions were warranted: (1) That there was a general treatment of gout that should underlie every variety, whether in the form of acute, subacute or chronic, aberrant or minor, and independently of special manifestations that required special treatment. (2) Colchicum in conjunction with the salicylates, or their congeners, or the alkaline carbonates, should hold their place in the treatment of acute gout. (3) In the aberrant form, so varied were its manifestations, there could be no specific treatment. (4) In the other forms medicine played a subordinate rôle to diet, and the iodides were the main remedies. (5) Our knowledge of gout was not yet sufficient to justify us in adopting any ironclad rules to govern the general treatment. (6) Success demanded a study of the individual, his environment, his necessities, and his physical limitations.

Dr. WM. H. THOMSON opened the discussion by stating that laymen looked upon uric acid as a disease, and one which alarmed them, and, when suffering from it, asked what they could do to be saved. He said that for the past ten years there were far too many medical journals, and he was much surprised recently when his mail brought him *The Uric Acid Monthly*. He referred to the prevalent confusion that existed regarding the relation between uric acid and disease, and he began his discussion by challenging the question whether or not purin bodies were the sole origin of uric acid. He spoke of the existence of uric acid in almost a pure state in certain reptiles and birds, and said that some animals lived and ended their days in making nothing but uric acid. Uric acid was really the cause of nothing in man; when it existed in large quantities there was always a *plus* before it which did the harm. Depending upon that *plus* harm followed. In childhood we may have the uric acid gravel. Often patients may have uric acid gravel fo years and years, and yet never have an attack of gou He said he wished to present to the society four defini tions as follows: (1) True rheumatism was always a infection by some specific organism which had alread been demonstrated. It was the microbe which caus acute articular rheumatism. (2) Gout was caused b the metabolism of certain articles of food and by nothin else. (3) There was a whole class of painful affection which was characterized by a myositis, or a fibrosis, or fibromyositis, in which the sheath of the muscles, i fibers or tendons were involved, and this was a form whic was frequently called muscular rheumatism. This w not true rheumatism, because it is not of microbic origi Lumbago, sciatica, etc., were generally classed und the head of muscular rheumatism, but they were direct connected with disturbances in the excretory functio of the liver (4) This was a class that could be confound with gout and lithæmia, on account of the frequent d posits of urates from the urine. This occurred, as a ru in those people who became exposed, and had a chilli of the body surface, as from exposure to rain, etc. Su cases, he said, were treated differently. Cod-liver o was almost a specific in such cases, and this was, in fac the reason for its introduction as a medicine by the fishe men of Norway. Uric acid producing gout was very d finitely connected with what was taken into the mout so much so that one could say that it was not produce by alcohol, AS SUCH, but by alcohol the result of ferme tation occurring within the body. He said that in En land everybody had gout; every physician, pathologi Haig included, never appeared to see anything but go as a cause of every ailment. Whereas in Scotlan where they imbibed whiskey freely, it was a rarity. Go was rare in Scotland, as it was, a few years ago, in th country. Since the introduction of beer here gout h become extremely plebeian, especially in New York Cit The more whiskey displaced by beer the more gout w encountered. Therefore, it was not the alcohol whi produced the gout *per se*, but there was something of fermenting character which produced it in all probabili Cider was a great gout producer. But, as a rule, the must be present that something *plus* the alcohol. Wh was it? He said we did not know. So many proble were yet connected with metabolism not yet solved th we were still in the dark regarding gout. The differenti diagnosis between rheumatism and gout was not ve difficult. If a man gave a history of his trouble beg ning early in life as a polyarthritic complaint, if his pul was soft and compressible, then it was probably rhe matism. If the trouble had been gout or a gouty co dition he would have full arteries, an incompressib pulse, dilated veins on the hands, etc., conditions just o posite to what one would expect to find in rheumatis Gout was a monoarticular affection at first. If it beg above the knees its diagnosis was more complicate There was one infallible sign he referred to, *i.e.* gou inflammation affecting a joint with condyles; in suc cases if one pressed with the fingers upon the condyl the patient would wince; but upon other parts of th joint it would not be noted. In rheumatism the pa was along the course of the tendons. In gout there wa a structural change. Gout always left its card. It wa peculiar to rheumatism that no matter how it infected a individual (90 per cent. of the cases were infected throug the tonsils), there was a fibroid thickening of some joint as a result, and the prognosis was invariably favorable

Dr. HARLOW BROOKS spoke of the increase of gout i New York City, especially noted at the hospitals, and h believed it was due to the increase in the beer-drinkin habit. It was more frequently noted by him now in th morgue than a few years ago. He agreed that it wa not the alcohol *per se* that caused the disease but the kin of beverage containing it. Whiskey ordinarily would not bring on an attack of gout. The simple fact that the

urine contained an abnormal amount of uric acid and purin bodies should not permit a diagnosis of gout being made. Another thing that led to mistakes was the fact that when the urine was examined and large quantity of substances found, as a rule little or nothing was known regarding what substances had been taken in the body as food; the finding of certain bodies in the urine was largely dependent upon the food taken in. This was a point that should always be considered.

He did not agree with the mechanical theory of the symptomatology or pathology. Reptiles and birds had enormous quantities of uric acid in their bodies, and without producing any ill effects at all. Uric acid in large quantities could be found when a person was in perfect health. In other words, in these animals the deposition of salts did not cause any pathological changes. He did not believe the mechanical theory accounted for the interstitial hyperplasia, nor for the nervous symptoms. He did not believe we knew the cause of the arteriosclerosis associated with gout. He said he could not draw a sharp line of distinction between gout and rheumatism, but he did not believe that rheumatism was purely an infectious disease or a specific one. So far as he knew, he thought that gout and rheumatism, from a pathologist's standpoint, were much confused.

Dr. FREDERIC E. SONDERN said that anyone who had examined a very large number of specimens of urine from both gouty and rheumatic patients would be impressed that, in the laboratory, both diseases should be divided into two groups at least. It was unquestionable that there were many cases of acute rheumatism in which the uric acid output was very great as compared to the output of urea; there were other cases in which the output of uric acid was considerably decreased. The same thing applied to gout. Whether this would have any bearing on the treatment of rheumatism he said remained to be seen. It was true that some cases of gout responded to definite methods of treatment which had no effect in other cases. This was true, too, in rheumatism, especially in the chronic or subacute varieties. In some cases salicylic acid will act well; in others the alkaline treatment does much better. To him it was a question whether the output of uric acid should be an indication as to treatment. He doubted that uric acid alone was the cause of the disease; for why did one meet it in excessive amounts in some cases and small amounts in others? A consideration of the ratio between urea and uric acid as seen in the literature was rather amazing, and he thought that the figures quoted in most books and articles were apt to be a little low for New York City. Recently it had been stated that this ratio was 1 to 40, and that anything under this ratio was abnormal. In other words, if there was more than 1 part of uric acid in 40 parts of urea, then we were having an increased uric acid output. Examination would rarely show this ratio to be above 1 to 40, and many fell between 1 to 35, or 40, and without apparent evidences of disturbed metabolism. There were many other conditions in which there was a disturbed uric acid output not necessarily the cause of the conditions, but evidence of disturbed metabolism. In acute yellow atrophy one of the first things noted was a diminution in the amount of urea, and a relative increase in the amount of uric acid. In pregnancy the examination of a large number of specimens shows a relative increase in the excretion of uric acid. What point was normal, and where it became abnormal, remained to be seen. This increase in the excretion of uric acid he looked upon as being evidence of disturbed metabolism. In the cyclic forms of chill and periodic headaches occurring in adults observations made showed that, during the normal periods, the urea and uric acid ratio was normal, 1 to 45; but as these people approached the attack the uric acid and urea ratio became 1 to 45, 1 to 50, 1 to 60, and, as he once saw it, 1 to 92. Then came the explosion. When the attack appeared there was always a marked deposit of uric acid, scanty urine, etc., and the ratio became 1 to 12, 1 to 8, and, in one case he saw, 1 to 6. During the convalescent stage the ratio went up again to near the normal. He asked what was considered the normal ratio? For a long time it was taught that the normal daily amount of urea excreted for an adult was from 20 to 40 grams. Dr. Cabot stated last year that it did not make a particle of difference how much was excreted in averages, but it depended upon the intake; that the estimation of the amount of urea was, as a rule, useless. This went to the other extreme.

Dr. P. A. LEVINE spoke of the origin of uric acid in the body and its relation to gout. He agreed with Dr. Thomson that uric acid arising from the purin bodies was rather doubtful. In any part of the body where uric acid accumulated it might be due to one of two processes: first, a hyperproduction, and secondly, a diminution in the combustion of it. He compared uric acid and rheumatism with sugar and diabetes. Glycosuria did not always imply an attack of diabetes; sugar in the urine might be simply due to faulty kidney function. Sugar in the urine might show an increase in the production of sugar; again it might be due to the fact that normally produced sugar was not oxidized. The same was true of uric acid in the urine.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

One Hundred and Eighty-seventh Regular Meeting, Held March 4, 1904.

DR. CHARLES STEDMAN BULL, PRESIDENT, IN THE CHAIR.

A Case of Giant-celled Sarcoma of the Lower Jaw Treated by Radium; Preliminary Report.—Dr. ROBERT ABBE showed a young man of seventeen years with a view to having the members watch the course of growth or retrograde under radium treatment of a tumor, regarded by surgeons as the most malignant known.

Four months ago the lad noticed the swollen gum around the left lower canine tooth, which became loose, and which he thought was only temporarily inflamed.

For two months it increased in size, until he sought advice at Saint Luke's Hospital—with the following condition:

A soft spongy dark tumor occupied the lower jaw from the middle toward the left, and bulged inward under the tongue and outward under the skin—the inner part one-third of the mass, and the outer, two-thirds.

In bulk it measured 3 cm. from front to back; 6 cm. on the front surface of the jaw, and 3 cm. vertically (1 in. x 1½ in. x 1 in.).

To the finger pressure within and without it seemed almost to fluctuate, it was so soft.

Within the mouth it rose behind the teeth and presented a small ulcerated surface.

Three teeth were loose and bent in their places, so that a pair of thumb forceps could have easily pulled them out of the tumor that had absorbed the alveolar around them.

A piece was removed from the inner side for examination and proved to be a pure giant-celled sarcoma.

Surgically viewed, the case called for resection of the jaw with hopeless mutilation, and inevitable recurrence.

I decided to try a strong radium specimen upon it.

A small glass tube of 10 cgm. of the 300,000 x Curie radium was applied over the growth within the teeth for one-half to one hour daily, a lead shield protecting the tongue.

On the fourth day the purple ulcerated surface became flat, pink, and small. The entire bulk of the projecting internal tumor was considerably reduced.

I then began to attach the outer part by laying the tube between the lip and the tumor. Three such applications blistered the mucous membrane, and I decided to penetrate the mass of the tumor. Anæsthetizing the mucous membrane with a drop of cocaine I pressed a bistoury

through the rim of the tumor and found the soft sarcomatous mass allowed the radium glass tube to be pressed through it down to the lower margin of the jaw, represented by the shell of bone.

Two or three times weekly I have thus penetrated the various parts of the tumor, leaving the radium imbedded for two to three hours at a time.

The growth of the tumor has not only been arrested, but there is an appreciable shrinkage in bulk of about one-third of its original size during the two months of treatment. In quality also the substance of the growth has become much firmer, bleeds scarcely at all, and presents a gritty feeling, as if points of ossification had set in.

Summary.—Growth of tumor apparent, two months—treatment during the next two months by radium only.

Arrest of development, undoubted shrinkage of one-third in total bulk. Apparent retrograde in active growth of tumor. Treatment now being continued to be reported two months later.

Dr. JOSEPH D. BRYANT called attention to the presence of an enlarged submental lymph node in the corresponding side of the neck, and suggested that it be removed and examined. If that also proved to be cancerous, very little good could be expected from the radium treatment.

Appendicitis in Children.—Dr. JOHN WINTERS BRANNAN read this paper. (See page 685.)

Dr. HENRY F. WALKER said he thought the reason why comparatively few cases of appendicitis in children came under the surgeons' care was that the attacks in early life were usually of the catarrhal type. The condition was analogous to inflammations of the urethra. A man would have his first attack of gonorrhœa, and usually recovered without a stricture. After his second attack he is likely to have a stricture, and after his third attack he is very apt to have one. With appendicitis, the early attacks are usually ascribed to indigestion or colic, due to some indiscretion in diet, but after repeated attacks the inflamed appendix becomes strictured, and when it is no longer able to empty itself, the formation of an abscess was likely to occur. Severe attacks in adults are the outcome of milder attacks in earlier life. Dr. Walker said he had seen a number of cases of appendicitis in children. In one of them, a boy of three years, there was an abscess that was at first supposed to have originated in the hip-joint. It was evacuated, and there was apparently a complete recovery, but thirty years afterward another abscess developed, the origin of which was traced to the half obliterated appendix.

Dr. WALTER B. JAMES thought there was no doubt as the reader of the paper had suggested that a great many cases of appendicitis in young children did not reach the surgeon, because the condition is not recognized by the attending physician; and this not because the obvious symptoms were overlooked, but rather because of the inherent difficulties in the way of the diagnosis in these patients.

The complex of symptoms, described for instance in Dr. Brannan's case, could hardly have been recognized as belonging even probably to appendicitis. In the diagnosis of this condition, the conclusion is based, for the most part, upon information obtained directly from the patient rather than from the result of objective investigation.

The complaints of young children are so vague, and their replies to questioning so uncertain and varying, as to introduce an unusual element of doubt into such a diagnosis. These children are subject to many minor attacks similar to that described by Dr. Brannan, but which arise from moderate disturbances of the stomach or intestines, and from mild errors in diet, so that the early recognition of appendicitis in young children must always probably be difficult, and in many cases impossible.

Dr. EDWARD G. JANEWAY said he had seen a number of cases of appendicitis in children, one of them in a child two and a half years old, which was operated on successfully. In some instances, as in the case reported by Dr. Brannan, the diagnosis was very obscure. About four years ago he saw a child that had been under the observation of several men, including a surgeon and a specialist in children's diseases, and each one had arrived at a different conclusion. There was evidently a very decided infectious process, and possibly peritonitis, but there was no abdominal tenderness (although morphine had been given), and the consensus of opinion was that it was not appendicitis. The child died and the autopsy showed general infection following appendicitis. Dr. Janeway said he had heard of another of a girl of six, who awoke one morning with the remark, "Nurse, I have appendicitis." An operation on the following day proved that her diagnosis was correct. In that instance the child's cousin had recently been operated on for the same disease. The speaker said that pain on the left side of the abdomen was not so uncommon in appendicitis, and he recalled a case in a girl of fourteen where the pain and tenderness were especially severe on that side, and seemingly indicated the presence of a peritonitis. The white cell count at that time was not very high—12,000. A gynecologist was asked to examine the pelvic organs and found nothing wrong. There was now some rigidity of the abdominal muscles, and the white cell count had gone up to 13,000. The next day the child began to vomit and the cell count was over 20,000. The abdomen was opened, and the cæcum and appendix were found in the pelvis: they were both covered with a fibrinous exudate, and the appendix was the seat of an unperforated ulcer. Peritonitis had already set in, and death occurred two days after the operation. In that case, the pain on the left side was due to the dragging upon the inflamed small intestines.

Dr. ANDREW H. SMITH said that in obscure or doubtful cases of appendicitis the suggestion made by Dr. Meltzer might prove of value. The suggestion was to put the psoas and iliacus muscles into action by having the patient lie on the back and causing him to elevate the leg without bending the knee. By this action the muscles were contracted considerably thickened, and anything resting upon them would be elevated and could be felt more distinctly.

Dr. GEORGE L. PEABODY said that in many of these cases the symptoms were so obscure that they were not likely to be operated on very early unless we took the ground that an operation should be done early in every doubtful case, providing the services of a thoroughly competent surgeon could be obtained. In children, the usual symptoms of appendicitis, such as pain, vomiting, and fever, were often the result of indiscretions of diet. In connection with the general subject of appendicitis, the fact was becoming more apparent daily that it was extremely important to operate early, even in doubtful cases, on the ground that an early operation in the hands of a competent surgeon was extremely unlikely to do any harm if a normal appendix were found and might prove a life saving measure if the appendix were diseased.

Dr. JOSEPH D. BRYANT said that while he had to do with many cases of appendicitis in children, the condition was comparatively rarely seen in early life, and he was inclined to explain this fact in the same way as Dr. Walker did. Some years ago, the speaker said, he had conducted a rather thorough investigation along the line of determining the contents of the appendices of post-mortem subjects and he had found that in quite 65 per cent. of those cases in whom death had occurred from various causes, the appendix was the seat of a distinctly morbid process, in some instances containing a series of strictures, while others were still able to expel their contents. The diagnosis of appendicitis in children was usually obscure, pain and tenderness and tension, particularly the latter, being the most reliable symptoms. The result of operative procedures in these subjects was usually very good.

Dr. BEVERLEY ROBINSON recalled a case of appendicitis in a child, seen many years ago, in which there was a distinct abscess formation. The patient was operated on by Dr. William T. Bull, and recovered. Since then, the

speaker said, he had often had occasion to feel extremely anxious over children who presented symptoms of obscure abdominal trouble; some of them, no doubt, had appendicitis, others, perhaps, styphlitis or colitis, but in all of them recovery took place without operation.

Dr. Robinson said he still felt skeptical that the condition which we term appendicitis should limit itself to this rudimentary organ. An analogous condition could not be found in any other organ in the body. Why should the appendix continually become the seat of an inflammatory process, and leave the cæcum and colon unharmed? The mere removal of the appendix, followed by the recovery of the patient, did not prove that the neighboring gut was not involved in a general inflammatory process, which was formerly recognized under the name of typhlitis or colitis. The speaker said there undoubtedly were cases of inflammation of the appendix in which we had nothing better to offer the patient than an operation. He always favored the use of a proper laxative in these cases, preferably hydrargyrum cum creta, which he thought was a far better remedy than calomel in children. It was extensively used in the children's hospitals in London.

Dr. Robert Abbe said he thought the number of cases of appendicitis in children that came to operation was very small compared to those in adults, for the reason, as had been already suggested, that the appendix was rarely strictured sufficiently in early life to produce a complete blockade. The pathological process often began in infancy, but the organ retained its power to expel putrid material until adult life. The speaker said he had seen many cases that gave a history of recurring attacks of appendicitis dating back twenty-five and thirty years, and upon removal of the appendix he had found this long-standing strictured condition. He recalled a case in a child of three years in which a concretion of exfoliated epithelium was found in a tightly strictured appendix. During the last two or three years he had seen at least half a dozen cases of acute appendicitis in which there was no stricture, but a follicular ulcer, and a hemorrhagic condition of the mucosa of the appendix. These he was inclined to regard as an infection by the bacillus of influenza, and a complication of what the late Dr. Draper referred to some years ago as abdominal grippe.

Foreign Body in the Œsophagus.—Dr. Joseph D. Bryant reported this case and showed the specimen. This consisted of a fragment of gutta-percha paper-cutter, 7½ inches long, which the patient, a robust Irishman, had accidentally lost hold of while he was illustrating to his friends the art of sword-swallowing. An examination showed a little bloody mucous in the mouth. Upon introducing a bougie into the œsophagus, a certain degree of adhesion between the bougie and the paper-cutter was noticed, both instruments being made of the same materil. When the finger was introduced into the throat, nothing could be detected, but suddenly the patient gagged severely, and at that moment the paper-cutter was felt to touch the end of the finger. This procedure was then repeated, with the same result. A pair of long forceps was thereupon introduced open into the œsophagus for a distance of about six and one-half inches, and closed when the patient gagged. Luckily, the foreign body was caught between the blades and extracted. Dr. Bryant said he had estimated that the expulsive force of the diaphragm during the act of gagging had raised the paper-cutter at least half an inch, and brought it within touch of the finger. Since the length of the tube from the diaphragmatic narrowing to the upper incisor teeth is about 14½ inches, and his finger was introduced 6½ inches, leaving half an inch between the end of the finger and upper end of the object in the quiescent state.

Death Following Puncture of the Lung in Thoracentesis.—Dr. George L. Peabody reported this case. The patient was an old man who had long been in feeble health. In addition to extensive pleural adhesions, with effusion, he had a weak heart and chronic nephritis. On account of the dyspnœa from which he suffered, his left pleural cavity was tapped by his physician, as had been done once before, and 900 c.c. of fluid withdrawn. His dyspnœa was immediately relieved, but about an hour later it recurred with increased severity, he became cyanotic and died in a few minutes. When Dr. Peabody saw him, just before his death, the left pleural cavity did not act freely; the heart was displaced; succussion was not obtainable; the coin phenomenon could be heard over the lower part of the chest only.

A fine trocar and cannula had been used in tapping the chest, and the autopsy showed that the lung had been punctured. Dr. Peabody said the case was extremely uncommon, as he thought the lung was frequently pierced in the operation of thoracentesis without producing any particular harm. Perforation of the lung and the introduction of air into the pleural cavity usually did not cause more than temporary inconvenience. In this case the lung was collapsed as far as its adhesions would allow it.

Dr. W. Gilman Thompson said he thought it was extraordinary that death should have resulted so suddenly in this case, because the pleura was usually very tolerant of air. He had under his observation at present, at Bellevue Hospital, a man with pulmonary tuberculosis who, four days ago, had developed a double pneumothorax, producing considerable displacement of the heart and dyspnœa. In order to relieve the dyspnœa, the pleural cavity was punctured, when the air escaped with sufficient force to blow out a candle. The man was still living and fairly comfortable, although the final outcome of the case is inevitably fatal.

Dr. Peabody said that in most of these cases there was a history of pulmonary tuberculosis. In the case he had reported, the man had suffered from chronic bronchitis and chronic pleurisy. The pleural adhesions were so dense that it necessitated a good deal of rough handling before the lung could be removed. This might have accounted for the certain amount of blood found in the pleural cavity at the time of the autopsy, but there was no doubt about the ante-mortem puncture of the lung.

Dr. Thompson, in order to illustrate the tolerance of the pleural cavity for air, said that several years ago he had the opportunity of examining a number of cases of pulmonary tuberculosis that had been treated by Dr. H. P. Loomis by the introduction of nitrogen gas into the pleural cavity through an aspirating needle, the object being to rest the diseased lung through compression. A dozen or more cases were treated by that method, and in no instance was there marked dyspnœa, or even any special inconvenience. Some of the patients were up and about the ward immediately after the gas had been introduced. Dr. Thompson said he thought the common practice of aspirating the pleural and peritoneal cavities with a sharp needle, and leaving it in during the process, should be condemned. It was better to use a small cannula, which could be left in safely. The danger of leaving a sharp needle in the pleural cavity was that as the fluid was withdrawn the lung rubbed against the point of the needle and was liable to be punctured.

Dr. Janeway mentioned the case of a man with empyema in which the small cavity was being irrigated with peroxide of hydrogen. On two occasions, after these washings, the man suddenly became temporarily hemiplegic. His head dropped forward, and the hemiplegic condition persisted about half an hour. The speaker said he had subsequently found a number of similar cases reported in French literature, and he had come to the conclusion that in these cases, in which the pleura was usually greatly thickened, oxygen or air was drawn into the heart, and thence passed to the brain. Dr. Janeway said he had seen exploratory puncture of the chest followed by pneumothorax on several occasions.

Joint Meeting of the Chicago Medical and Chicago Orthopedic Societies.

At a meeting held March 30, 1904, Dr. Weller Van Hook exhibited a man with multiple lipomata of the neck, and a little girl upon whom he had operated for double congenital dislocation of the heads of the radii. Dr. L. L. McArthur showed a patient upon whom he had operated for compound comminuted fracture, associated with dislocation of the ankle-joint.

The remainder of the program was devoted to a symposium on "Tuberculous Spondylitis." Dr. Edwin W. Ryerson discussed the "Etiology," and among other things said that the disease was most prevalent among the ill-nourished children of the poor, living in localities where they were exposed to tuberculous infection, in overcrowded and insanitary dwellings. A large proportion of such children were shown at autopsy to have glandular tuberculosis, even though no clinical manifestations might have existed. A clear hereditary predisposition had been demonstrated in from 25 to 70 per cent. of cases of Pott's disease. Both sexes were about equally represented, boys being slightly more numerous than girls. The portion of the spine most frequently affected was stated by Taylor to be the cervical region, but most other observers considered the junction of the dorsal and lumbar regions to be the most vulnerable.

Dr. John L. Porter discussed the "Diagnosis and Prognosis." He said until the diagnosis was made, efficient, intelligent treatment could not be instituted. With an early diagnosis, not only was the treatment made more effective and the prognosis improved, but the patient might often be saved a distressing deformity which added to an already crippled existence the burden of mental suffering and pain. He believed that a diagnosis of spondylitis could and should be made in every case before any deformity had appeared. He considered the signs and symptoms of spondylitis in detail with relation to the different divisions of the spine. In the prognosis, one had to consider: (1) The factors concerned in the prognosis were the time at which the diagnosis was made and the treatment begun. (2) Individual resistance to the disease. (3) The patient's age. (4) The patient's environment. These, with the location of the disease in the spine, were the chief points in determining the prognosis.

Dr. John Ridlon discussed "Straightening of the Curvatures of Tuberculous Spondylitis." After mentioning the methods of straightening of curvatures in these cases, he related his personal opinions and conclusions to which he had arrived from his experience.

Dr. Wallace Blanchard spoke of the "Present Status of the Mechanical Treatment of Spondylitis," and stated that a set of principles based upon the most approved mechanical means of treatment might be formulated, although the extent to which they could be carried out varied in each individual case. First, to remove the superincumbent weight of the body. Second, to prevent flexion and rotation of the spine. Third, to put the greatest possible amount of pressure upon, or in the immediate vicinity of, the deformity compatible with the integrity of the skin. Fourth, to very thoroughly hyperextend the spine. It was believed that the application of these principles placed the spine under the best possible circumstances for healing, with the least possible amount of deformity. The author showed a plaster jacket with chin rest; a Taylor back brace with head supports; a brace for cervical spondylitis partially applied, with the chin nearly touching the chest, and a brace for the treatment of cervical spondylitis.

Dr. Alexander C. Wiener presented a patient upon whom he had operated for gravitation abscess. Recently, in a large psoas abscess, reaching down to the middle of the left femur, which originated in a tuberculous spondylitis of the first and second lumbar vertebræ, he had used a large trocar to empty the pus. The man, thirty-four years of age, was attacked seventeen years ago with tuberculous spondylitis, which left quite a kyphosis of the lumbar spine. For seventeen years the patient did not experience any inconvenience, when, without apparent cause, the tuberculous process revived, resulting in a large psoas abscess which bulged forward at Scarpa's triangle. Just behind and below the left great trochanter was found a small swelling the size of a silver dollar. This spot was chosen for three preliminary injections of carbolic acid, six drops each time, five and seven days apart. Carbolic acid seemed to have powerful chemotactic qualities, since it allured the pus to the outer side of the femur. One pint of thick pus intermixed with chunks of fibrinous coagula and fine osseous débris was emptied the first time. Then fifteen drops of 95-per-cent. solution of carbolic acid was slowly injected into the abscess cavity. The operation was repeated six times at intervals of one to three weeks. The last injection was made three months after the first one, when the fluid had changed into a clear yellow serum. At no time was there any harm experienced, either local or systemic, and the injections seemed to cause no pain or inconvenience.

Dr. A. E. Halstead said that the surgical treatment of Pott's disease comprehended (1) the removal of the tuberculous focus in the bone; (2) the treatment by incision or by puncture of the abscesses that are secondary to the bone disease, and (3) the operative treatment by laminectomy of the most serious of all of the complications of this disease, namely, the paraplegia resulting from pressure upon the spinal cord. The author's experience in the operative treatment of paraplegia due to spinal caries had been limited to two cases, which were detailed, one of which recovered and the other died. He said laminectomy was contraindicated in cases in which there was tuberculosis of any other organ. In one of his cases the lung and pleural tuberculosis probably existed before the operation, although its presence was not recognized. The duration of the paralysis offered no contraindication to the operation, as it was not so much the length of time that the cord had been subjected to pressure, as the way in which the pressure was exerted that affected the integrity of the cord and determined the possibility of recovery.

The general discussion was participated in by Drs. M. L. Harris, Frederick Mueller, Wallace Blanchard, Alexander C. Wiener, Edwin W. Ryerson, L. L. McArthur, and John L. Porter.

Cincinnati Academy of Medicine.

At a regular meeting, held March 28, Dr. Gilbert L. Bailey presented a boy of twelve who had suffered at the age of one year with anterior poliomyelitis, with paralysis of right leg and arm. The arm recovered. When first seen by Dr. Bailey the leg was flexed on thigh, the knee partly dislocated outward and backward, and the foot was held in a position of equino-varus with flail-like movement of the ankle-joint. All the muscles controlling the knee were useless, except the biceps and semitendinosus at the ankle, only the gastroenemius remained. On January 27 tendon transplantation by the Lange method was done. The tendons of the biceps and semitendinosus were loosened, elongated by means of No. 12 braided silk, passed subcutaneously along the anterior surface of the patella and implanted in the periosteum at the insertion of the patellar tendon. The tendo Achilles was divided, one half being lengthened by the Bayer method to correct the talipes equinus, the other lengthened by a No. 12 silk extension which was inserted into the periosteum at the middle of the inner surface of the foot to correct the eversion. After three weeks in plaster passive movements were begun and now patient is able to walk with a cane and the improvement still continues. Dr. Bailey also presented a man of thirty-five with a double pes carus, who had had contracted extensors of the toes, so that the toes could not be made to touch the floor, the entire weight of the body having rested on the os calcis and the ends of the metatarsal bones. Patient complained of constant soreness of the feet. The condition was greatly relieved by

itting and lengthening the extensors of the toes and the e of insoles to more evenly distribute the body weight.

Dr. C. L. Bonifield presented a fibroid of the uterus eighing nineteen pounds, which he had removed from a lored woman of forty-four—she had noticed the tumor r eighteen years. It extended clear across the abdomen, using protrusion of both flanks. On March 16 it was moved with great difficulty and now patient is well on e road to recovery.

Dr. C. A. L. Reed presented a rectum which he had moved from a woman of twenty-four at the City Hospital. The rectum was prolapsed for the extent of four ches and was associated with complete laceration of the rineum. The prolapse was irreducible and had been for six weeks. The surface was ulcerated and the mass thickened and hardened as to feel like a malignant owth. The entire prolapse was removed and with it e torn and ulcerated sphincter ani. At a second operan the laceration of the perineum was repaired and by eans of figure-of-eight sutures the inner portion of the ator ani was made to form a new sphincter. At esent patient has complete control except when the wels are excessively loose. Dr. Reed also presented ovarian cyst which he had removed after it had been angulated by torsion for four days. The diagnosis was de before operation.

Dr. B. Merrill Ricketts presented twelve specimens of pendices removed at operation. In one patient, a male, pain and tenderness was upon the left side, low rn in the abdominal cavity. Appendicitis was not spected. Incision made on left side for exploration aled nothing abnormal except the greatly diseased adherent appendix, which was drawn over and removed ough the incision on the left side of abdomen. In other case the appendix was one inch long, greatly inmed and curled upon itself like the letter S, attacks re frequent and severe for eighteen months with loss twenty-five pounds. The third case, a man of forty-six ars, operated upon for large scrotal hernia in January der cocaine, had three attacks of pain in right lower domen during convalescence; course was not delayed r appendicitis suspected. During the past two weeks e family physician found tumefaction in appendicular ion, with tenderness and other signs of appendicitis. eration two days ago showed hernia wound in good ape, the omentum was adherent to anterior belly wall d constituted a mass three times the size of fist. The pendix was found within this tumor and was removed; was five inches long, club-shaped and obliterated, conining no pus. Patient died thirty-six hours later in llapse, no cause could be assigned. The history dated ck fifteen years, but pain had always been referred to e hernia.

Dr. Rufus B. Hall presented the tubes and ovaries which had removed from a case of tuberculous peritonitis, they re markedly tuberculous. Later he had to open and in an abscess external to the kidney. Patient is doing ll, but final outcome is not yet certain. Dr. Hall also esented a tube distended with bloody fluid which he d removed. At the operation it was thought this might an ectopic gestation, but further examination had shown to be a simple hæmatosalpynx.

Dr. Frank Fee reported a case of cæsarean section. s. M. B., twenty-one, had suffered from rickets in childod. She became pregnant for the first time in Septemr, 1903, and was admitted to City Hospital June 17. atient is 4 ft. 4 in. tall, has very bad teeth, the sternum prominent, as are the junctions of ribs with sternum. e pelvic measurements are intertrochanteric 29 cm., tercrestal 26½ cm., interspinous 26 cm., external conjute 15 cm., and internal conjugate 8 cm. After several ttacks of false pains, labor began on August 3 at 8.30 A.M. ead of child could be felt in upper right quadrant and et at the os. Fetal heart sounds were loud and clear to e right of umbilicus. At 12.30 membranes ruptured, and as labor did not progress and patient wished a living child, cæsarean section was done. After sterilization patient was chloroformed and incision made by Dr. Fee from one inch above navel to symphysis. Uterus was brought out, broad ligaments compressed by assistant and uterus incised. Child and placenta were rapidly delivered, uterus swabbed out with 1-15,000 adrenalin, and uterus closed with chromicized catgut. Recovery was uninterrupted. Child was healthy and weighed 7 pounds, with a length of 20 inches. Measurements of the child's head were: occipito-mental, 13 cm.; occipito-frontal, 11¾ cm., biparietal, 8¾ cm.; cervico-bregmatic, 9½ cm., and bitemporal, 7 cm.

Dr. W. D. Haines reported a case of fractured patella which had been treated by rest for ten days and then the fragments sutured by a quadrilateral subcutaneous suture. The suture was passed subcutaneously across through the ligamentum patellæ, then reëntered through the skin and passed up external to the joint, and then in the same manner passed through the quadriceps tendon and down to the place of starting. He showed skiagraphs and said the functional result had been perfect.

Dr. J. W. Withrow reported a case of unusual infection. The patient, a young married woman, had suffered pain and had not menstruated since birth of a child eighteen months before. A physician was called and chloroformed her to do some operation, patient claims not to know what, but finding her pregnant did nothing. She aborted that night. Nearly two months later patient was seen by Dr. Withrow, she was markedly septic. Examination showed uterus to be fixed, with foul purulent discharge from cervix. To the right of uterus high up was a mass the size of an orange. Under an anæsthetic the sound showed the uterine cavity to be normal in size and fairly clean. Further investigation disclosed a channel opening into cervical canal just below the internal os. Into this an œsophageal bougie was passed for thirteen inches, apparently behind the peritoneum; the end was palpated just behind right kidney. An incision was made over end of bougie and a pus cavity found extending up behind kidney and down to the brim of pelvis. Long drainage tubes were used and patient left the hospital well four months later and has remained so. Dr. Withrow thinks the false opening was made in an attempt to produce abortion.

Dr. B. Merrill Ricketts then showed skiagraphs of a five-year-old girl with fracture of middle of fibula and tibia at the age of one year. The deformity was angular, no correction having been permitted. After taking these skiagraphs deformity had been corrected by osteotomy.

A Rare Case of Pulmonary Hernia in a Baby of Three Years.—Saba Frontini gives a résumé of the subject of pulmonary hernia illustrated by a case in a child of three years. Pulmonary hernia occurs through the intercostal spaces or the diaphragm, and appears as a mass lying covered with the skin of the chest wall. It is a rare condition. It may be traumatic, consecutive, spontaneous or congenital. It is produced by force from within, as in coughing when the glottis is closed, and there is a forcible expiration, or in singing. The congenital form occurs on the front of the chest, near the sternum, in one of the upper intercostal spaces. The consecutive form occurs from the first to the fifth intercostal space, at the lower angle of the scapula. The spontaneous occurs below the clavicle. The opening through which the hernia comes is small and fibro-muscular in form. The coverings consist of the skin, subcutaneous connective tissue, thoracic and intercostal muscles, the pleura and any new formation that may have occurred. Causes are emphysema, bronchial catarrh, tuberculosis, pertussis, and congenital malformations. It may or may not be reducible, and generally increases rapidly in size. This case occurred after pneumonia, followed by empyema. The chest was rachitic in form.—*Rivista di Clinica Pediatrica*, March, 1904.

Books Received.

A New Method of Suspending the Uterus.—Bardescu describes a method of suspending the retroverted uterus intended to avoid the undesirable features of the procedures commonly in use. The abdomen is opened either by a median incision or by Küstner's suprapubic incision, adhesions separated and the fundus brought forward. A hole is pierced through the rectus muscle on either side and a loop of the round ligament pulled through with forceps. The peritoneum and muscle are sutured and the two protruding loops of round ligament stitched together in the mid line.—*Zentralblatt für Gynäkologie*, No. 3, 1904.

Medical Items.

Contagious Diseases—Weekly Statement.—Report cases and deaths from contagious diseases reported the Sanitary Bureau, Health Department, New Y City, for the week ending April 23, 1904:

	Cases.	De
Measles	1630	
Diphtheria and croup	391	
Scarlet fever	436	
Smallpox	2	
Varicella	83	
Tuberculosis	381	
Typhoid fever	29	
Cerebrospinal meningitis	...	

Observations on the Changes, the Pathogenesis and Uropoiesis of Diabetes Insipidus.—Alfredo Rossi give results of his observations of three cases of diabete sipidus. Of these, one first had symptoms after an dent resulting in a severe wound of the scalp. T symptoms continued for ten years; then grew better, returned after severe labor. Another had pulmo tuberculosis. All three had the classical symptom diabetes insipidus. The writer made observations d a number of days, dividing them into two periods; i first period the diet was one rich in albuminoids, wh the second the carbohydrates predominated. The albuminoids in the urine and fæces oscillated from d day, but not more than in the normal subject. chlorides also did not differ materially from the no The curve of the phosphates followed closely that o albuminoids, and showed nothing abnormal. The am of water eliminated corresponded closely with th gested. He tested the relative freezing points of and urine, and found that that of urine was much than that of blood. Hence he concludes that in patients there was a urine of great abundance, with specific gravity, a molecular concentration much in to that of the blood, containing no abnormal subst and having the normal solids in a customary amount *Policlinico*, March, 1904.

The Treatment of Obesity.—P. Grocco gives the fo ing rules for the treatment of obesity: He con obesity to be the result of an excess of ingesta or of rangement of the metabolism of the body. The cli must first ascertain the cause of the accumulation o then regulate the income and outgo so that the equalized, and combat the morbid effects of the condi As a general rule the liquids taken at meals sh be reduced, and liquids taken two hours after meal. Some cases, however, do not get along well this reduction of fluids, but gastric, intestinal, renal symptoms ensue. In cases in which the uri habitually concentrated and has deposits of urates or acid, a dry diet is not well borne. In such cases best to allow frequent small meals, four or five in twenty-four hours, with liquids taken two hours each meal. The diet is reduced until the weight o patient falls to the desired figure, and then kept at requisite amount to maintain a normal weight and pre a renewed increase. There should be a great increa muscular activity by walking, riding, cycling, sport gymnastics. General and local massage, when the domen is enlarged, is very useful. Hydrotherap measures, cold and heat, are important, as well as bonic acid gas baths. Patients should sleep very m rately, and should not do excessive mental work. halations of oxygen may be used with advantage. author does not advocate the use of purgatives, alka or other drugs in reducing weight, except as the condi of health would naturally demand them, as in cas the need of laxatives, iron in anæmic and alkalies in g cases.—*Rivista Critica di Clinica Medica.*

THE PHYSIOLOGICAL FUNCTION OF MENSTRUATION AND THE PART PLAYED THEREIN BY THE FALLOPIAN TUBES.*

BY J. RIDDLE GOFFE, M.D.,
PROFESSOR OF GYNECOLOGY AT THE NEW YORK POLYCLINIC, ATTENDING GYNECOLOGIST TO THE CITY HOSPITAL, ETC.

In discussing any function connected with menstruation we are met at once with the obstacle that neither scientists nor clinical observers are agreed among themselves regarding the significance of menstruation, its cause, or the end to be accomplished. Menstruation was formerly regarded as the exclusive prerogative of woman, but we now know that woman shares this privilege with monkeys in captivity, including all members of the monkey tribe. This function has always been associated more or less intimately with the reproduction of species, although the ancient idea was that menstruation was a cleansing of the system by which woman got rid of all noxious products that might be lurking in her physical economy. This belief has given rise to numerous popular superstitions. One of them is that a drop of menstrual blood will wither a flower, another that a menstruating woman in a dairy turns the milk sour, and another that no menstruating nurses should be allowed in the operating room during a laparotomy. I am informed by Dr. Blair of Monroe, N. C., that among the large German community in Union County of that State no menstruating woman is allowed to put her hands in the sour kraut barrel—the common necessity of every household. But why a woman should require this monthly housecleaning, for which man had no necessity, has never been satisfactorily explained.

The monthly molimen has certainly a striking analogy to the heat or rut observed in all mammals. Arthur Johnstone of Cincinnati has made extensive comparative studies of rut and menstruation. He defines menstruation as a shedding, getting rid of some material whose function is fulfilled, and for which the economy has no longer any use. It is an analogous process to the molt of birds, the shedding of hair and horns by the deer, the shedding of the leaves by a tree, etc. All warm-blooded animals that stand or walk erect, without exception, menstruate. The appearance of the discharge is due simply to posture. The same process goes on in all quadrupeds, as the sheep, the cow, the dog, the cat, etc. Animals that go on all fours shed the same degenerated material, but on account of the position of the uterus it is retained in that organ and reabsorbed through the lymphatics into the blood and consumed in the vital processes or eliminated through excretory glands. The frequency with which this process recurs varies in different animals. In animals menstruation or shedding occurs after the rut has passed. In the monkey menstruation has been observed five times in a year, although no evidence has been given that she has the rut more than twice a year—in the spring and fall.

Wiltshire† states that the cow has a discharge at an interval of about three weeks, at times bloody, resembling menstruation, and that similar phenomena have been observed with other domesticated animals. In the cow, however, the rut occurs only once a year. Similar phenomena have been observed in the mare.

The cause of the greater frequency and regularity of this phenomenon in woman as compared with the lower animals is an interesting question. We know that in the lower animals unless impregnation occurs during the rutting season, the phenomenon of menstruation occurs, a period of rest follows, upon which supervenes a gradual congestion till the period of rut recurs. It has been suggested that this frequency in woman is due to her environment, and is the result of civilization and its attendant luxuries. Life under these circumstances becomes more artificial; every factor in life is sought as a source of pleasure, and the race becomes more sexually inclined. We know that animals will not tolerate the male except at a time when impregnation is possible, while civilization permits of this indulgence simply as a source of mutual pleasure.

Dr. Ritchie, who was followed in his views by Lawson Tait, scoffed at the idea of any logical or causal relation between ovulation and menstruation. Previous to their time M. Gendrin and Dr. Robert Lee conducted a battle royal in their discussion regarding the true and false corpora lutea and their relations to menstruation and pregnancy. Lawson Tait tells us that this lasted for fifty years, and in its progress resulted in the destruction of many animals, and yet the outcome was undecided.

As I view the phenomenon of menstruation in its broad and general factors, it seems to me that it is a direct and logical sequence of ovulation in which pregnancy has not occurred. Menstruation is usually defined by our best authors as a monthly hemorrhage. Duane defines the menstrual molimen as the endeavor by the generative organs to produce a menstrual flow, molimen coming from moliri, to strive. Were I to offer a definition of menstruation I would say that it is a frustrated attempt on the part of nature to reproduce an individual of the species. Its *raison d'être* seems as follows: An ovum is thrown out from the ovary and gradually finds its way toward the uterus; nature at once begins preparation for its reception; the nervous system becomes exalted to a high degree of functional activity; the blood supply to these parts is increased; the endometrium, which is the soil in which the ovum is to be implanted, becomes turgid, soft, and velvety; its epithelial cells swell and multiply, and every preparation is made to nourish the welcome guest and give it a home. If perchance this guest has been annointed with the baptism of the spermatic fluid, she is ready to respond to this bountiful preparation and partake of the nuptial feast; but if the sacrament of baptism has been

*Read at the regular monthly meeting of the Clinical Society of the New York Polyclinic Medical School and Hospital, April 4, 1904.

†"Comparative Physiology of Menstruation."

omitted, the guest is incompetent to receive the hospitality extended, and is therefore cast out. The preparations are also eliminated; the exuberant epithelial cells are exfoliated; the delicate capillaries, already engorged with their vitalizing wine of life, sweat drops of blood by diapedesis or burst and discharge their contents; the congested and engorged glands secrete and excrete profusely, and this mingled mass of epithelial cells, blood, and mucus comes away in the form of menstrual blood. So that the discharge is simply an evidence of the retrograde physiological process that is going on in the organs within. Briefly stated, the arguments confirming this idea of the direct relation between ovulation and menstruation are as follows: (1) The appearance of menstruation at puberty marks the stage of sexual maturity, at which time fecundation becomes possible. (2) The cessation of menstruation, the menopause, marks the end of the child-bearing period; as a rule fecundation is no longer possible. (3) It is a common observation among obstetricians and gynecologists that women go many years, during which they are bearing children, without once menstruating during that period. This is undoubtedly due to the fact that ovulation ceases during pregnancy and lactation, and the first ovum that appears in the renewed activity of ovulation becomes fertilized, and continues its process of development into a new individual. In my history-book I have notes of many cases in which the women have gone from seven to ten years, during which time they were bearing children, without menstruating. If now it should happen that a girl married before any menstrual discharge has appeared, she might become impregnated and by a rapid succession of pregnancies never menstruate at all or, indeed, not till late in life. D'Outrepont, quoted by Edgar, reported a birth in the ninth year of age without the establishment of menstruation. Ahlfeld reported the case of a woman who bore eight children without ever having menstruated. He has also narrated a case of a woman who had never menstruated, but who bore a child in her thirty-second year. This dependence of menstruation upon the non-fertilization of the ovum is supported by the opinion of such eminent authorities as Loewenhardt, Reichert, and Hiss.

Coming now to the question propounded in the title of our paper, the source of the menstrual discharge is to be accounted for. Does it come entirely from the uterus or does the fallopian tube participate normally in this function. Lawson Tait, I think, was the first to announce that the fallopian tube, as well as the uterus, had a part in this process as an assigned physiological function.

Anatomically there seems to be every reason why this might be true. The mucous membrane lining the tube is of the same general structure as the endometrium, although it possesses no glands and no submucosa. We know from the numerous cases of tubal pregnancy that the mucous membrane of the tube is capable of taking on the functions of the endometrium, developing a placenta and carrying on the nourishment of the fœtus as far as the capacity of the muscular walls of the tube will permit. If, then, the tubal mucous membrane makes the same preparation for the reception of the ovum as is normally provided by the uterus, why should it not undergo the same retrograde process in case of non-impregnation that the endometrium undergoes—namely, a shedding of its epithelium and a rupture of its capillaries? The most recent literature on this subject is that furnished in a paper by Drs. Montgomery and Bland of Philadelphia, who reported a case illustrating the point. The case was that of a woman who had been operated upon ten months previously by abdominal incision for intrapelvic abscess. Shortly after leaving the hospital a small abdominal sinus developed in the line of the old abdominal incision almost simultaneously with the establishment of the succeeding menstrual flow. The material discharged from this opening was at times comparatively nil, but during the days preceding the menstrual period the discharge increased in quantity, became bloody, and assumed all the characteristics of menstrual fluid. Upon opening the abdominal wound the fimbriated end of the right fallopian tube was found adherent to the abdominal cicatrix. The author is persuaded, from the phenomena manifested by this patient during menstruation, that the tubal mucosa undergoes changes similar to the uterine mucosa and participates in the menstrual function.

As contributing to the evidence in favor of the participation of the tube in the menstrual function, I have to present two unique cases that have occurred in my private practice.

Case I.—Mrs. K., a Jewess, age thirty-four, married sixteen years and the mother of one child twelve years of age, has had frequent induced miscarriages. She was submitted by me to operation for multiple fibroids of the uterus, attended by menorrhagia. The operation was vaginal hysterectomy, in which the appendages of the right side were also removed on account of disease, the left ovary and tube being left *in situ*. The vaginal incision was left open and the pelvis packed with gauze. This gauze, in accordance with my custom, was gradually removed day by day up to the seventh day, when the last of it came away. Convalescence was uninterrupted and the vaginal vault closed apparently in a most satisfactory manner. At the return of the first menstrual period following the operation, the patient experienced the usual phenomena of menstruation, her breasts swelled and became sensitive, and there was a slight blood-stained discharge from the vagina lasting for a day or two. Nothing was thought of this until the recurrence of the molimen the following month. The same symptoms recurred and likewise the blood-stained discharge. She reported at my office, and thinking the discharge might be due to some granulations in the vaginal scar, I inserted a speculum and found a reddish spot in the left angle of the vaginal incision. I touched this with stick of nitrate of silver and applied a cotton tampon, assuring her that she would have no further appearance of menstruation. To my surprise she presented herself the following month with the same history, and upon examination I found the same angry looking circumscribed surface, and upon careful examination was able to pass a small silver probe for the distance of three and a half inches. It occurred to me then that this was the proximal end of the fallopian tube that had been drawn down by the gauze in its extraction and become incarcerated in the vaginal scar. I kept her under observation for the two following months, the same experience supervening, and then, fearing the possibility of a tubal pregnancy, I made repeated applications of stick caustic deep in the opening until I had induced granulations and finally sealed up the tube.

Case II.—Mrs. H., the wife of a physician of New York City, who came under my care for excessive pain and menorrhagia. Upon examination I found a greatly enlarged, retroverted, adherent uterus, complicated by salpingitis of the left side. I

subjected her to vaginal section for relief of the condition in a private sanatorium in July, 1899. Upon delivering the fundus into the vagina multiple fibroids were discovered at the fundus, and upon undertaking myomectomy and incising the uterine wall it was found so studded with fibroid foci that, with the consent of the husband, a vaginal hysterectomy was done, removing the appendages of the left side, but leaving the ovary and tube of the right side *in situ*. The patient made an uninterrupted recovery, but the same accident that occurred in the first case was repeated here, but more fully, for the proximal end of the tube was drawn down into the vagina, and in the healing process projected fully one-quarter of an inch into the vagina. The patient was a marked neurasthenic, extremely nervous and excitable, and upon the return of her monthly molimen two months after the operation she noticed a bloody discharge, and having been told that she would never again menstruate, she presented herself at my office in great alarm. I was able also to probe this tube, but after keeping the patient under observation for three months and convincing myself by repeated observation that the discharge was an actual menstruation from the tube, I no longer felt justified in leaving the tube patulous. I therefore caught the end in an artery clamp, twisted and tore it away, and by repeated applications of stick caustic succeeded in closing permanently the vaginal opening.

Experience in these two cases seems to establish, as far as such observation can, the fact that the tube, at least in the absence of the uterus, actually performs the function of menstruation. How long this process would have continued I am of course unable to say, but in the second case the discharge came freely, and I actually saw drops of blood come from the tube.

My opinion is that the dominant factor in menstruation is the ovary and ovulation; that from the ovary, or its sympathetic nerve ganglia in the pelvis and abdomen, there springs the impulse for reproduction of the species; that menstruation is a retrograde process, the result of a failure of fertilization of the ovum, and that the tubal mucous membrane as well as the endometrium participates actively in the process of menstruation.

GALLSTONES IN THE COMMON DUCT.

By A. H. CORDIER, M.D.,
KANSAS CITY, MO.

The classification of gallstones according to their location has not been given the importance that their presence in special localities demands. From a clinical, pathological, and operative standpoint, this division of the discussion is essential. Many writers on this topic discuss the subject in a general way, and thus fail in a measure to call attention to, or lay stress upon, the most important phases of the pathology. Complications engrafted upon the original pathology are often more serious than the cause of the complications. In no locality is this more true than in neglected common-duct gallstone cases.

The majority of individuals who have gallstones in the gall-bladder are not made aware of their presence by any direct clinical manifestations. This is not the case when the stones are using the common duct as their resting place on their journey to the duodenum.

A stone, when once in the common duct, with rare exceptions, begins making mischief that is quickly noticeable by the patient and his physician, this evidence, with short intervals of quiescence, will continue until the offending foreign body is gotten rid of by nature or the surgeon, or until death of the patient from chronic cholæmia, carcinoma, or other complications. Recognizing the great importance of prophylaxis, the surgery should, especially in this locality, be timely and complete. I know of no clinical picture more perfect in its symptomatic details than that of complete or partial occlusion of the common duct by gallstones.

Most gallstones have their origin in the gall-bladder, but the purpose of this discussion is to treat of their effects after once formed and while in the common duct. I am firmly of the opinion that when a stone has once invaded the common duct it never returns to the gall-bladder. I do not wish to be understood, however, as in any way depreciating the importance of surgical treatment of stones in the gall-bladder when known to exist.

I cannot fully agree with some of the noted authorities when they say that an inflammatory process is ever present and necessary to put a common duct stone in motion, and that the wedging of the stone in the duct is a direct result of this process. I see no reason why a stone too large to pass through the duct should not become lodged as a similar concretion does in any other location—for instance, a stone in the ureter.

With the pressure of the liver in its effort to force the bile through its natural canal, I see no reason why the stone should not only be set in motion, but by its presence, produce a complete occlusion and a most severe pain from nerve-stretching and pressure. It is true, the liver is an expansive organ, but there is a limit to this, and that limit is aided by nature in her endeavors to prevent a foreign and poisonous fluid (bile) from entering the circulating blood in that organ.

Two pints or more of bile forced into the blood through resisting capillaries within twenty-four hours must of necessity mean quite a firm pressure at the point of stone obstruction.

I would rather accept the theory that the friction of the stone on the delicate epithelium of the duct leads to a destruction of the same, and thus acts as a direct cause of local inflammatory changes and opens an avenue for constitutional sepsis at this point.

The clinical symptoms in their order of appearance would in most of my cases support this theory. The patient has an attack of pain, then a chill (when a chill at all) followed by fever, and a day or two later evidences of absorption of bile in the deposit of the coloring matter in the skin (jaundice). The stone occludes the duct, bile pressure against it produces in turn nerve pressure (pain), and destroys the surface epithelium; absorption takes place, and a rigor followed by fever is the result of this absorption.

The presence of a long-imprisoned gallstone in the ductus communis choledochus undoubtedly is a factor in the production of cancer of duct and adjacent structures. One author (Schroeder) claims that cancer occurs in 14 per cent. of gallstone cases. This percentage, I believe, is too high. Carcinoma is not as likely to develop here as in the gall-bladder.

Jaundice from a stone obstruction is usually less pronounced and persistent than that produced from a carcinoma. A stone producing icterus is more likely to have periods of quiescence than a growth—in fact, a malignant stenosis is usually progressive and permanent.

The pain varies f om a mere transient uneasiness (rare) to the most intense and prostrating suffering lasting for hours or days. A stone too large to pass through the papillæ into the duodenum may give rise to the most terrific suffering, followed by a

quiescent period for a number of months and then by another attack. Now let this same stone remain in the duct for years or until it has increased materially in size, and the pain produced by its presence will in all probability be less severe than that caused by the smaller stone.

The duct gradually becomes accustomed to its presence, and dilates, nerve sensibility is in a measure obtunded and tired out—nature accepts the situation, so to speak. The bile may find a groove or depression, through which it may escape into the duodenum and the patient live a fairly comfortable life for years.

Now let a severe infection take place about this stone, and the duct is again occluded, pain is renewed, jaundice reappears, and the clinical picture of a total stoppage of the common duct is presented again. The calculus does not change its position during this process, the inflammatory symptoms subside, and the patient is left as before.

The pain produced by a common-duct stone is usually much nearer the median line than that produced by stones in the cystic duct. Absence of bile in the fæces (acholia) is usual at some time in the history of these cases, and is a companion to jaundice. The rigors produced by a lithogenous choledochus obstruction resemble those of malaria in their periodicity and are not governed by the amount of the local inflammatory process as much as by the location of the stone A stone lodged near the entrance of the duct into the duodenum will cause more systemic septic disturbance than if located elsewhere in the biliary tract. The largest number of absorbents are located here, and the close proximity to the intestine containing the colon bacillus admits of more ready infection at the site of the stone.

The colon bacillus and other intestinal bacteria I believe are less virulent at this point than lower down in the canal; this is demonstrated by the comparative safety with which the infected bile may escape at time of operation on the common duct. This weakening of bacterial powers in all probability is due to the action of the bile either alone or in conjunction with the pancreatic and gastric juices.

One thing is certain, a larger amount of bile containing bacteria can be spilt into the peritoneum with safety at this point than can be tolerated by the peritoneum from a similar leaking of an appendix or an intestine. I have not stitched the gall duct in many of my cases, I have seen a half pint of muddy-looking bile-stained fluid escape from the common duct at the time of the operation, staining the intestines, omentum, and peritoneum over a large area, in spite of my precautionary wall of gauze; but not in a single case has there been the least evidence of a peritonitis.

I have relied in all my cases upon gauze drainage to conduct the escaping bile to outside dressings. Bacteriological examinations have revealed the colon bacillus in most of the cases at the time of operation. Many cases with latent common-duct stones are diagnosed as gastric ulcer, gastralgia, or cancer of pylorus. A careful analysis of the symptoms present and the weighing of the negative evidence will, in most instances, lead to a correct opinion. The injury to the pancreas from gallstones is often of such a character as to retard recovery after the cause has been removed. Interstitial pancreatitis of the duodenal end (head) of the pancreas and pancreatic stone formation and cancer are the most frequent changes induced in this organ.

Case.—Mrs. B., age forty-eight. Twelve years ago had a severe attack of hepatic colic lasting two or three days, this was followed by a marked jaundice, the latter lasting two or three weeks. In the course of a few months a recurrence of the colic was experienced, and with it the jaundice. These attacks of colic have continued to return every two or three months. Two years ago the jaundice became persistent and every few days she would suffer from colic.

The fæces were white in color and putty-like in consistence. The last two or three months she has had occasional mild rigors and a slight rise in temperature (101° F.). She has lost much in weight; the pulse is 56 per minute; the patient is thoroughly jaundiced. Examination revealed no enlargement about the gall-bladder and but very little tenderness. Diagnosis of common duct stone made. Operation: Incision to the right of the rectus beginning near the sternum. The gall-bladder was contracted and empty, there were no adhesions about the duct. The foramen of Winslow was easily reached. A large round stone (one inch and a quarter in diameter) was detected in the portion of the common duct just before it disappears behind the duodenum. The cavity was well walled off with gauze, and with two fingers of the left hand in the foramen the duct with the stone was pushed toward the surface of abdomen and divided with a scalpel and the stone removed. With the fingers underneath the duct and stone, thus pressing the stone to the surface of the duct, the portal vein and hepatic artery and their branches were pushed to one side and removed from danger. The stone was easily detected at the thinnest point, and here it is safest to cut directly down upon it. An abundance of bile escaped through the opening, coloring the surrounding structures in spite of the precautionary endeavor to protect them with the gauze. No effort at duct-stitching was made. Gauze was carefully placed about the opening in the duct for drainage and the gauze packing placed in the abdomen at the beginning of the operation was removed. Part of the surface wound was closed in the usual way. The gauze was not all removed for a week or ten days, for if the gauze is taken out too soon nature will not have her walling off work completed. At the end of two weeks bile ceased to flow from the wound. At the end of a few days evidences of bile were detected in the fæces; the skin regained its natural color. The patient left hospital at end of five weeks, well.

I report the above case to bring out the cardinal principles in all common-duct stone operations. Each case must of necessity be dealt with according to the indications in that particular case.

In arriving at a diagnosis there are several pathological conditions occurring in this region to be eliminated, viz., cancer of the pylorus; gastric ulcer; stenosis of the pylorus; movable kidney; cancer of the head of the pancreas; chronic duodenitis (rare); growths pressing on the duct.

Cancer of the pylorus when so situated that it produces a pressure on the duct may cause a jaundice and pain simulating stones, but when the case is analyzed carefully a diagnosis is usually made. The length of time since symptoms first developed, character of the pain, the persistent gastric symptoms, and rapid inroads on the general health of the patient all point to cancer. The same applies to cancer of the pancreas, although the obstructive symptoms come on earlier and are more persistent in the latter. The presence of a small ulcer in the pyloric end of the stomach may mislead unless a close scrutiny of the symptoms is made.

A right movable kidney by pressing on the common duct may cause a slight and transient jaundice and some pain, but the presence of the kidney in an

abnormal position and the mildness of transitory obstructive symptoms will point to the correct diagnosis.

A chronic duodenitis (a very rare condition) may lead to an error in diagnosis. The distinguishing features are the absence of the severer symptoms of stone obstruction and a more marked tenderness over a larger area, accompanied by disturbed intestinal digestive symptoms.

DENTIGEROUS CYSTS.*

By CHARLES GREENE CUMSTON, M.D.,
Boston, Mass.

In considering the subject of dentigerous cysts, a few remarks on the pathology of the condition may not be out of place, as the literature is rather scarce relative to the condition under consideration. The first important work on the subject was published in 1872 from the pen of the well-known Parisian dentist, Magitot. After a careful study of all material he had at hand, Magitot gave a systematic classification of dental cysts, and at the same time he took their etiology into consideration.

As most of the writers who have studied this question since Magitot's paper appeared have concurred in most of the statements therein found, it would seem proper to consider his paper a little in detail. Magitot considered every cystic production lined with a membrane and situated in the interior of the jaws as a maxillary cyst. These cysts usually contain a fluid contents varying in nature from one case to another; they may be thin and fluid or, on the other hand, quite thick and pasty. Every cystic production arising spontaneously in the maxilla usually originates from a tooth. Magitot also believed that if a foreign body penetrated the jaw a cyst could form around it, and this fact has been proven by a case long ago published by Maisonneuve.

Cysts developing spontaneously he termed progenous cysts, and in contrast to these, those developing around a foreign body he termed perigenous cysts. To these two forms which develop in the bone substance he adds a third type, to which he applied the name of neogenous cysts, which develop outside the osseous tissue.

Magitot subdivided follicular cysts into embryoplastic, odontoplastic, and corona-forming-period cysts according to the time of their development, and he again subdivides them according to the nature of their contents into serous, colloid, and caseous cysts.

By the classification given, it is readily seen how Magitot accounts for the formation of progenous cysts. From some influence he believes that the enamel may perish in different stages of development by either resorption or by maceration. The dental sac then slowly develops by a proliferation of its structures. The contents found in embryoplastic cysts will be composed of shapeless embryonal dental elements, while in those of the odonto-plastic cysts more or less regularly developed tooth elements will be present, while in cysts arising during a later period of dental development coronal structures should be present.

Magitot believed that neogenous cysts arise in the periosteum of the root, and he supposes that this membrane undergoes development by proliferation of its cellular structures and thus forms a cystic sac. The primary causative factor is an obliteration of the canal of the root due to an inflammatory thickening of the periosteum following infection from the canal of the root or by formation of a denticle in the pulp. The epithelial lining of these cysts is derived from a marked proliferation of the connective tissue cells.

Although Magitot unquestionably did much to enlighten us on the question, he could not reconcile his theory with facts; namely, that the epithelium could arise as if by regeneration from the connective tissue elements. It was naturally most important to discover the true origin of the epithelium which is exclusively found in neogenous cysts when it has not become destroyed by a suppurative process of the contents of the cyst.

In 1885 appeared a paper by Malassez, and it is to him we are indebted, discovering in the maxillæ of embryos in different stages of development that during the period of the formation of the teeth there takes place, beside the physiological proliferation of the epithelium for the formation of the dental follicle from the embryonal enamel, other proliferative processes, arising both from the organon adamantinæ and from the mucous membrane. These epithelial masses are in structure exactly like the enamel organ, arranged around the root of the tooth in various manners. They are also found present in normal lower jaws of adults, and he came to the conclusion that these epithelial masses persist not only during the period of dentition, but are normallypresent during adult life. He asserted that not only the neogenous cysts of Magitot, but also every other neoplasm having an epithelial character developing in the jaw, especially multilocular cystomata and cystadenomata of the maxilla, originate from these masses of cells which he terms paradental epithelial débris.

The conclusions arrived at by Malassez were examined and found correct by other investigators. Von Brunn especially, has given a satisfactory explanation, basing his assertion on the writings of Hartwig, published in 1874, and he shows how the epithelial masses, preëxisting around the root of the tooth, become constricted by the fetal enamel organ, and from its connective tissue with the epithelium of the buccal mucous membrane. If Malassez's theory relative to the origin of periodontal cysts from the paradental cell agglomeration is correct, these cysts should occasionally be met with in their early stages, and, in point of fact, Witzel published a paper on cysts of the roots of the teeth in 1896, in which he fully describes them and gives a satisfactory explanation for the development of periodontal cysts. He points out that one occasionally finds tumors varying in size from the head of a pin to a pea in extracted teeth, especially when they are the seat of caries. These neoplasms are sometimes spherical in shape, at others egg-shaped, varying in their connection with the roots, sometimes being near and sometimes being distant, while occasionally they are pedunculated.

On section these small, grayish-white bodies will be found composed of one or more cavities containing serous fluids. Microscopically the external layer of these minute growths is composed of a rough connective tissue, then by a layer of tissue abounding in blood-vessels and leucocytes, while the cavities are lined with epithelium. The larger cystic cavities show a more evenly distributed epithelial layer, while in the smaller ones the thickness of the lining epithelium varies considerably.

We consequently are here dealing with a miniature cyst which on account of its diminutive size has never given rise to symptoms. The microscopical examination of well-developed cysts exactly corresponds with these small pathologic productions described by Witzel.

In the first case of dental cyst that I have to report, the lining membrane consisted of several layers of flattened epithelium, and outside of this was a con-

*Read by invitation before the Harvard Odontological Society.

nective tissue layer measuring about 1½ millimeters in thickness. Outside of this connective tissue layer was found another of connective tissue in which nuclei were easily distinguished. The history of the patient was briefly as follows: She was a well built girl of twenty-five, who had always enjoyed good health. About three years ago she noticed for the first time a small bunch under the left nostril. This small growth gave rise to no pain and grew slowly, and continued to do so until at the time of the patient's coming under observation the left nasolabial fold had completely disappeared, while a tumor about the size of a large walnut was found immediately underneath the labionasal fold. The skin covering the growth was movable, while the left nostril was pushed upward. By palpation, fluctuation could be detected.

Under ether narcosis the growth was incised, giving issue to a transparent serum. The opening was enlarged, and it was then found that a cavity existed between the nasal cavity and the antrum of Highmore into which the apex of the root of a small incisor was found protruding. After extraction of the tooth and the removal of a corresponding part of the alveolar process, the cavity was plugged with gauze and the skin incision united by wire sutures. These were removed on the fifth day and the patient was discharged well in three weeks.

It is easy to understand why we have a flattened epithelium in large cysts, while in the smaller ones cubic epithelium is present because it is well known with what ease epithelial cells adapt themselves to the amount of pressure brought to bear on them. In all the cases of dentigerous cysts which have come under our observation, the microscope has revealed practically the same histological structure, but in some instances the epithelial layers were so thick that the lining membrane of the cyst was readily peeled out from the cavity. Such was the condition found in the two following cases:

A healthy boy ten years of age had had what was called by the mother a swollen cheek for over three years. The swelling had apparently never given rise to any pain. It had slowly increased until at the time the boy came under observation the deformity was very marked. By palpation, a tumor the consistency of bone was found in the anterior aspect of the right superior maxillary bone. The nasal cavities were normal. Under ether an incision was made over the most prominent part of the growth, the gum was stripped back and the bone opened with the chisel. This led into a large cavity lined by a whitish membrane which was easily stripped off and removed. The cavity contained a light yellow serum, but no evidence of any tooth could be found within it. On account of the large size of the cavity, which might be estimated that of a small hen's egg, it was deemed more prudent to obtain drainage through the nose, so a communication was made with the right nostril and a drainage tube inserted. In terminating the operation, a portion of the anterior wall of the jaw was removed so that the cavity might contract more rapidly. Drainage was continued for a week, after which time the wound was found to be granulating nicely and the patient was discharged cured at the end of four weeks.

The next case was that of a man thirty-seven years old, who for about eighteen months had noticed the presence of a tumor situated in the neighborhood of the left wisdom tooth. The swelling was hard and had slowly increased in size. By examination an oval tumor was found situated in the neighborhood of the wisdom tooth on the left hand side and might have measured in size that of a large English walnut. Under ether the last molar on the left side was removed, and it was then found that we were dealing with a rather thick-walled cyst of the jaw. The cavity was split open with the chisel, and by exploration it was found to communicate with the antrum of Highmore. It was lined with a thick, whitish membrane which was easily removed by blunt dissection. Drainage was obtained by making an opening into the nasal cavity and a rubber tube was inserted, the cystic cavity being plugged with gauze. No evidence of a rudimentary tooth could be detected within the cavity. The liquid contents consisted of a thick, light yellow serum.

Now, if we assume that these periodontal cysts are produced by an irritative process arising from the paradental epithelial débris of Malassez, and that the cavities increase in size on account of an increase of their fluid contents, we have all the conditions found in cysts of long standing explained. A cyst will naturally grow in the direction of the least resistance, and since the root of the tooth is firmly lodged in the alveola process by its periosteum, the bone being less resistant gives way to the pressure. On account of the pressure on the surrounding structures produced by the growing cysts, the vessels and nerve supplying the tooth and periosteum of the root undergo pressure atrophy and resorption. Thus may be explained the absence of periosteum covering the root and the apices projecting into the cavity of the cyst, although their presence is by no means constant.

The perigenous cysts of Magitot can be explained by a foreign body directly in contact with, or in the neighborhood of, the so-called epithelial streaks of Brunn. This produces a constant irritation, which finally causes a proliferation of the latter, and to this type those cysts, in which fully developed teeth are found present, belong in all probability.

It is easily conceivable that a tooth which did not make its exit from the jaw from faulty position or some other similar circumstance becomes enclosed in the maxilla and at length plays the part of a foreign body, causing the epithelial streak to proliferate. It would appear that such cysts are generally considered under the head of follicular cysts, but under these circumstances it is difficult to explain the presence of fluid. But if we adopt Malassez's theory, it will be found to explain the formation of these cysts very well. One such case has come under my notice, the history of which is briefly as follows:

A woman sixty-four years old had had all her lower teeth removed several years ago. About twenty months before coming under observation, a swelling made its appearance on the angle of the right jaw. The tumor gradually increased in size, so that when the patient was first seen it was as large as an egg. Later a certain amount of pain had been felt in the growth, and the latter had become quite tense and the patient complained of much annoyance from a throbbing sensation more or less constantly present. Under ether an incision was made through the skin over the most prominent part of the growth, and while peeling off the periosteum of the ascending ramus of the lower jaw a cystic cavity was opened, giving issue to a considerable quantity of malodorous pus. The cavity was at once enlarged, and by digital exploration the root of a tooth was found protruding into it. The root was extracted, and the cavity was thoroughly curetted and drained. The patient made an excellent recovery, although drainage was necessary for over three weeks on account of a more or less abundant discharge of pus, but she eventually recovered without a fistula.

If a tooth develops normally, it is evident that it can never become entirely enclosed within a csyt, but its root may be contained within the cavity, and this is what is found in the larger number of cases. Most of the textbooks on surgery are very deficient in explaining the pathology of these cysts and even commit gruesome errors in their statements. It is an unimpeachable fact that one tissue can only reproduce itself, and consequently epithelium can only be derived from epithelium, and it is also well known that the lining membrane of these cysts is always epithelial and never composed of granulation tissue. Now Malassez theory explains satisfactorily the absence of the periosteal covering of the dental roots protruding into these cysts, but the cause giving rise to the proliferation of the epithelial streak of Brunn and to the formation of a periodontal cyst is not so easily demonstrated. Without any question an inflammation of the membrane of the root may be the starting point of this process, and many cases unquestionably do originate in this way. In such cases caries of the tooth, inflammation or gangrene of the pulp must have preceded, but if the root of a perfectly normal tooth is found protruding into a cystic cavity and where there is a complete absence of all signs of a periodontitis, or if no trace of tooth is found within the cavity of these cysts, such as has been observed, we consequently must admit that there are other causative factors existing. It is possible that traumatism may be the starting point of some of these cysts, because the lower jaw is particularly well placed to receive external injuries, and it is a well-established fact that retained teeth may be the cause of periodontal cysts. But it is also well demonstrated that a perfectly normal tooth may be the etiological factor when such a tooth is deviated from its normal position, an example of which will be found in the following case:

A boy seventeen and a half years of age had always been fairly well excepting for the ordinary ailments of childhood. For the past eighteen months he had suffered more or less intensely from toothache. About five months ago he first noticed a slowly growing tumor on the left side of his cheek. The growth did not give rise to any pain. Examination showed that the tumor extended from the left nostril underneath malar bone. The skin covering the growth was not reddened and was found freely movable over the tumor. The teeth were in extremely bad condition. The left upper canine appeared healthy, but it pointed directly backward in an oblique direction. At this point the superior maxilla presents a swelling extending from the labial to the palatinal aspect. Crepitation could be elicited on pressure. Under ether an incision was made over the tumor attacking it from inside the mouth, and when the cavity of the cyst was opened a large amount of thick, ill-smelling serum made its exit. The opening into the cyst was enlarged, the cavity being found lined with a smooth, glossy membrane. The apex of the root of the canine tooth was found protruding into the cystic cavity and was extracted. The alveolar edge was chiselled away and the cavity packed with gauze and drained. The patient made a rapid and uneventful recovery. Examination of the tooth extracted showed that the apex of the root was bare of its periostium.

On the other hand, the retention of developed teeth does not necessarily produce the formation of a cyst, as has been proven by several cases reported in literature. In one case reported by Hildebrand, that of a boy during his second dentition, he removed from the upper and lower jaws over two hundred perfectly developed teeth without any evidence of cystic formation around any of them.

It would also appear that the period of dentition may also play an important part in the etiology of periodontal cysts, and this should not seem surprising because at that time processes of resorption and regeneration are taking place everywhere in the maxillæ. Now, during such a time of active metabolism there is no reason why an increased activity may not be present in the epithelial streak of Brunn.

In many cases, periodontal cysts do make their début during the period of the second dentition, but in other cases the cyst begins to develop long before this period, as has been proven by certain cases reported in the literature. The second case narrated in this paper in all probability enters into this class, because evidently the cystic formation commenced at an early time in the dental development, and in point of fact microscopical examination showed a picture closely resembling an embryonal dentinal sac. This type of cyst may always be suspected if the tooth corresponding to it is absent, and this is an important point to be noticed in making a diagnosis. It may also occur that although the entire set of teeth is intact, a supernumerary tooth follicle may undergo cystic transformation, but such instances must be very rare. The cause of the cystic transformation is as yet unknown.

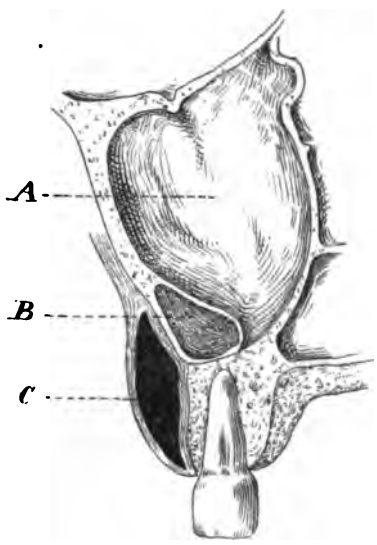
It may not be out of place to refer, in a few words, to a certain class of tumor which perhaps in reality does not strictly belong to the subject of this paper, but whose histological nature and origin is closely allied to that of periodontal cysts. The tumors to which I refer are usually encountered in the lower jaw near its angle. They suddenly begin to develop after they have been present for a number of years in a latent state, so to speak, and when they commence to increase in size they do so very markedly. Traumatism is usually the cause of their sudden increase in size and growth. After they have attained a certain size they present symptoms of cysts, namely, fluctuation and parchment crepitation. These cysts have been treated by incision, curettage, and drainage, which has rarely been the means of curing them, and in most instances an extensive resection of the jaw has been necessary.

These cysts have been described by a number of surgeons. Some of them were multilocular while others were unilocular. Microscopically they are found composed of small cavities or canals, the inner wall of which is lined with an epithelium of the cylindrical, cubic, or polygonal type, while in the larger cysts it is flattened. Malassez believes that these cysts also originate from the paradental epithelial débris, but the reasons why in one case a simple periodontal cyst should develop, while in others cystomata or cystadenomata arise, is as yet insufficiently explained, but a large number of authorities agree that the original epithelial cells of periodontal cysts originate from the enamel organ, while the other types of cysts take their origin from the buccal mucous membrane.

As I have already stated, the development of dentigerous cysts is caused by the increase of the fluid contents which is evidently constantly secreted by the lining membrane of the cyst, and the development of the growth naturally extends in the direction of least resistance. The bony structures of the jaw enveloping the cyst become thinner and thinner until finally they entirely disappear by pressure atrophy and then the cyst assumes a soft consistency. If the cyst continues to grow, the soft

parts covering it become thin, and finally the cyst ruptures and its fluid contents are evacuated spontaneously. This, however, rarely happens, because operative interference is usually undertaken before such a marked development has been reached. I have had one case of this description, which I will here briefly report:

A man aged thirty-two years had complained of an inflammation of the buccal mucosa covering the root of the first molar on the left side about eighteen months before coming under observation, and at the same time he noticed a swelling appearing under the left nostril. A few weeks later the tumor opened spontaneously and a considerable amount of pus escaped. On examination a fistula was found near the root of the first left molar, and the patient stated that the swelling would increase in size and then give exit to quite an amount of pus, after which it would decrease. The pus was always discharged through the fistula. When the tumor would increase in size on account of the collection of pus within it, it gave rise to a certain amount of pain. In other respects the patient was entirely well. The skin over the tumor was movable and not reddened. An incision was made over the tumor, including the fistulous opening, which gave exit to a yellowish fetid pus. The anterior wall of the alveolar process was resected and then a cavity lined with a membrane was exposed. The cyst sac was carefully dissected



A—Empyema of sinus.
B—Dentigerous cyst.
C—Dental abscess.

out and the cavity packed with gauze. This was removed in three days and the patient was discharged well in eighteen days.

The fluid contents of these cysts are usually serous, and it is only after secondary infection of the cyst has taken place that the liquid becomes purulent. Infection can occur very easily from the buccal cavity or from the remains of teeth within the cyst. In those cases in which decayed roots protrude into the cystic cavity, infection may also arise from the canal of the root.

Regarding the diagnosis of dentigerous cysts, it may be said that when the growth has reached a certain size but little difficulty will be experienced. We will here find a circumscribed unilateral swelling of the bone giving rise to a parchment crepitation and a fluctuation. If there is any doubt, an exploratory puncture will in most instances give issue to a serous fluid. In the early stages of the process, when the swelling of the bone is of small dimensions and the tumor hard to the feel, the diagnosis is less easy, because in this condition the cyst resembles any circumscribed tumor of the jaw. The absence of the various forms of fluid collections occurring in the upper jaw.

If the cyst should burst into the antrum of High- abscess, but if the topography of the parts be remembered an erroneous diagnosis can hardly be made, and the figure, taken from the excellent "Manuel de Diagnostic Chirurgical" by Duplay, shows extremely well the relationship betwee pain during the entire progress of the growth will al one in making a differential diagnosis. Dentigero cysts might be mistaken for cystomata, but it shou be remembered that the latter class of growth pe tain almost exculsively to the lower jaw. Suppura ing dentigerous cysts may simulate an alveol more, a primary empyema of this cavity will ari and *vice versa*, an infected cyst of the superi maxillary opening on the outside might eas simulate an empyema of the antrum if the cystic s protrudes into the cavity, completely filling it.

The prognosis of dentigerous cysts is in ever respect benign. The only serious complication th might arise would be when a cyst of the lower j becomes infected, because the danger then would that the pus might extend and infect secondarily o of the large veins of the neck; but this is only a su position of my own, for I must confess that I ha been unable to find any such instance recorded.

The treatment of these cysts is simple. Th should never be punctured unless for diagnostic pu poses, and after this, when the diagnosis has be made, operation should be immediately undertak In undertaking the surgical cure of these cysts it absolutely necessary to remove all vestige of t lining membrane, otherwise a relapse is practica certain to arise. In order to do this, the cav should be freely exposed by a large opening, and t curette, scissors, and, if necessary, the therm cautery should be freely used, because if any epith lial cells remain within the cavity they can regen ate and cause recurrence.

After the cavity has been thoroughly cleared of lining membrane it should be plugged with gauze a few days, so that the epithelium of the buc mucous membrane and the granulations aris within the cystic cavity unite when the lat becomes filled and only leaves a slight trace beh it.

If any tooth or root is found protruding into cyst it should be removed. In large cysts it may necessary to drain through the floor of the nose, was done in one or two cases here reported.

When dealing with these cysts developed in lower jaw, it is oftentimes impossible to reach tumor by way of the buccal cavity and it must attacked through a cutaneous incision. In t case it is indicated to remove as much of the lin membrane of the cyst as possible, and to accomp this a sufficient resection of the outer shell of bo should be done.

871 Beacon Street.

Intestinal Syphilis.—Suarez de Mendoza calls atten to this affection apropos of a case of rebellious chr diarrhœa which was cured by large doses of merc (hermophenyl) given by hypodermic injections. concludes that intestinal syphilis is an affection far rare than is ordinarily believed. Intestinal syp attacks especially the terminal part of the small inte and the large intestine. The symptoms of this affec are so few and so inconsistent that the diagnosis is d cult. Physicians, as a rule, are not on the lookout this disease. In every case of rebellious chronic diarrh the writer believes it to be well to think of syphilis, eit hereditary or acquired, and to apply the indicated tre ment.—*Gazette des Hôpitaux Civils et Militaires*, Mar 17, 1904.

A CASE OF RECURRING MEMBRANOUS STOMATITIS, ASSOCIATED WITH ERYTHEMA EXUDATIVUM MULTIFORME (HEBRA).*

By LOUIS E. BLAIR, M.D.,
ALBANY, N. Y.

The rarity of these cases in medical literature warrants the writer to put the following case on record: L. W. O., a lad about twelve years of age, undersized for age, poor muscular system and somewhat anæmic, family history on father's side good, on mother's side the nervous element is very prominent, never had any of the children's diseases except chickenpox. I was called in May, 1899, to attend him for the first time. He had numerous sores in the mouth resembling very much the mucous patches of syphilis. The irregular ulcerations were for the most part on the gums running into the teeth and on the hard palate, also a few sores on the tongue, under the tongue and on the buccal surfaces, on the lips and contiguous parts. Probably one-third of the mucous surfaces of the mouth was involved. There were extensive salivation, a heavy putrid odor, and involvement of the lymphatic nodes and glands of the face, neck, chin, and jaws. The sores were covered with a well-marked membrane, thick and firmly adherent, and diphtheria-like in appearance. The tongue was swollen and could not be protruded. The soft parts about the mouth and throat were much infiltrated and made swallowing difficult. After the stomatitis had lasted six days and was at its height an erythematous rash broke out extensively over the body, on the extensor surfaces of the extremities, back of hands and dorsum of feet, accompanied with a severe conjunctivitis of both eyes. The patient's temperature ran high, pulse weak and rapid, and general condition of prostration severe. In a few days the soft parts about the eyes were infiltrated and the conjunctivitis assumed a diphtheria-like invasion, and the eyes were closed. The character of the erythematous eruption was marked in that instead of having an ordinary papillary type with diffuse redness, the eruption became vesicular, confluent, and large blebs and bullæ formed, resembling for the most part scalds from steam or hot water. In the face the eruption was confluent, resembling variola, while again on the body in places the blebs became hemorrhagic and pustular, also some took on the form of herpes iris. There was but very slight itching, and desquamation did not take place until later on, when the eruption was fading out.

The eruption was quite extensive over the body, somewhat less on face and neck. The eruption in the mouth did not occur all at once, but seemed to come out in successive crops and spread. The peculiar phase of the case was the appearance of the skin affection at least one week after the mouth disease, and the question naturally arose what relation did the skin complication have to the oral disturbance; was the secondary involvement a part of the same infection. The patient was very ill for two weeks, and was as much prostrated as though he had a severe typhoid fever. Prof. Ernest Schwimmer[1] says, "that herpes iris, with its related forms, is usually a non-pyrexial affection, but sometimes it assumes a grave type, like the multiforme erythema, in which case the skin affection plays a prominent part; Wunderlich,[2] Gerhard,[3] and others have reported instances in which multiforme erythema appeared on the body with every indication of a grave typhoid affection, together with a high fever; the eruption subsequently changed into vesicles and presented a picture of herpes universalis. On the whole such observations are rare." As to the severity of this case at this time the views of Schwimmer are also to the point. "A less favorable prognosis is presented by the grave pyrexial erythemata with complicating diseases of the mucous and serous membranes. Experience shows that the erythemata connected with erythematous nodes of the mucous membranes run a grave course and at times end fatally. Hebra makes mention of such a case in which the autopsy showed infiltrations of the mucous membranes of the intestinal tract which he connected with the cutaneous erythema. Grigorow not long ago described a case of erythema attacking the skin and mucous membranes which led to ulcerations in the mouth and finally ended fatally." From these quotations from Schwimmer it is apparent that this authority did not meet with such a case in his extensive practice and could only cite two cases in his reading experience of the special literature.

This present illness lasted four weeks, when the boy made a slow recovery. The skin eruption in healing left bluish red and afterward coppery stains, which were noticeable for months afterward before they faded away. On the face there was loss of skin substance, and scarring resulted. In the mouth the sloughing of the mucous membranes was quite marked and white contracted scars could be seen a year later.

About one year after the first attack, in the spring of the year, the boy had a second attack much milder than the previous one; it consisted of a few ulcerations on the hard palate, under the tongue, on the gums, also on the lips. A few days later a few scattered erythematous patches becoming vesicular appeared on the face, neck, and hands and feet; also an eruption on the conjunctivæ, and at the inner canthi of the eyes. The mouth and eye eruption was covered with the usual membranous deposit. This attack lasted about two weeks, and yielded promptly to local washes and gargles. The systemic disturbance was mild. A third relapse came in June, 1901, and also lasted two weeks, and was very much similar to the previous one.

A fourth attack, and the severest one of all, appeared March 26, 1903, and lasted six weeks before the patient was in a normal condition again. The eruption broke out as usual in the mouth, a few sores appearing about the gums up to the margin of the teeth, and spread rapidly in the next few days, involving pretty nearly all the mucous surfaces of the oral cavity as far as the uvula; some of the ulcers were discrete, but for the most part confluent; profuse salivation, fetor oris, and infectious involvement of the glandular system of face and neck. The sores in the mouth were all covered with a firmly adherent membrane in spite of vigorous gargling and washings with H_2O_2 and early applications of nitrate of silver solutions. In five days the entire mucous surfaces of the oral cavity were nearly covered with a well organized diphtheria-like membranous deposit; the tongue, on account of its severe swelling, could not be protruded, and occupied a large part of the mouth space, pressing up against the roof of the mouth. The following day the nares throughout their whole length, the nasopharynx and contiguous parts, the oropharynx, larynx and trachea became involved, and the lumen of the larynx very much compromised, so that breathing during two days was very labored, and resembled that of severe laryngeal diphtheria. The conjunctivæ were also infected,

*Paper read before the Medical Society of the State of New York.

and the soft parts about the eyes œdematous and infiltrated, making it impossible to open them. The mucous membrane about the anus and glans penis and urethra were also covered with a membranous deposit.

About eight days after the manifestations of the mouth symptoms, an erythematous eruption made its appearance over the entire body, except on the hairy scalp, palmar surfaces of hands and soles of feet. The eruption on face was very profuse, became rapidly vesicular and confluent; the inflamed condition of the skin, together with a hemorrhagic serum which filled the vesicles, gave the characteristic appearance of virulent confluent variola.

The eruption covered from one-quarter to one-third of the entire skin surface of the body, and varied in size from a millet seed to large bullous patches, some being 1½ inches long, and ½ to 1 inch wide. The outer layer of the skin was lifted up, and there was a very free secretion of serum; some of the skin lesions were deep enough to destroy the true skin and had a blood-tinged serous secretion. There were successive crops of eruption, new ones appearing before the old ones had healed, giving the picture in places of erythema iris. Dr. Curtis saw the case in consultation at this time and pronounced it as worthy of illustration in any skin atlas. Both ears were entirely covered with large blebs and were much swollen, having the appearance of being scalded. Drs. Bloomer, Ward, and Bendell also saw the case, the former making bacteriological studies of the secretions of the mouth and skin. For the intense swelling of the glands at the angles of the jaw and under the jaw a 5 per cent. Oleat hydrarg. was rubbed in. Twenty-four hours after the application the skin became very much inflamed and was covered with almost one continuous crop of large blebs as though the skin resistance had been weakened. By the 10th of April the severe mouth, nose, throat, and laryngeal symptoms abated, and the temperature and pulse were falling, and it was thought the patient was convalescing, when a troublesome bronchitis developed and the pulse and temperature began to rise again. A fine crepitant râle could be detected next day along the base of both lungs. In the next thirty-six hours a lobular pneumonia was established. The pneumonia was of a wandering type and involved various parts of both lungs. In five or six days the pneumonic process cleared up and the patient convalesced. The desquamation of the skin was very extensive. The eyes healed slowly, as also did the mucous surfaces about the penis and anus.

On September 1 there was another moderate attack of sore mouth, accompanied with a membranous deposit and the usual lymphathic infection. This lasted one week. There were a few erythematous spots on face which became vesicular.

On October 17 the sixth attack of stomatitis occurred. The eruption appeared on the buccal surfaces, on the gums, on the tongue, hard and soft palate, and was covered with a firmly adherent membrane. The lymph nodes of the skin and glandular structures were all infected again in three days. On the fourth day both eyes became involved again, and there was a moderate erythematous eruption on face and neck. This attack lasted ten days. The nose and nasopharynx were not involved, the eruptive processes being confined to the mouth alone.

The bacteriological report from the Bender laboratory was as follows, September 30, 1903: Hæmoglobin, 85 per cent.; red cells, 5,240,000; white cells, 7,000.

A differential count of 240 cells showed the different varieties of leucocytes present in the following proportions: Polynuclears, $42\frac{9}{10}$ per cent.; small mononuclears, $36\frac{8}{10}$ per cent.; large mononuclears and transitionals, $16\frac{6}{10}$ per cent.; mast cells, $\frac{4}{10}$ of 1 per cent; eosinophiles, $3\frac{8}{10}$ per cent.

There was no marked anæmia in the red cells. The examination is practically negative, there being no marked anæmia nor disproportional increase of any of the varieties of white cells. The mononuclears are usually relatively more numerous in children than adults. We have on three separate occasions made a bacterial examination of material from the sores of the mouth; one of these examinations was made two years ago; one about a year ago and one at the time of the above examination. The organisms found had been cocci only. In the last two examinations these were of the staphylococcus pyogenes aureus class. In the first examination some streptococci were found.

Very truly yours,

ARTHUR T. LAIRD.

A word as to the treatment and to prophylaxis. The general treatment for fever, etc., was symptomatic; for the mouth weak solutions of Ag. NO_3, 1 or 2 per cent.; for gargling and cleansing, H_2O_2, diluted 1 to 2 or 3, had the best effect; for the nares and upper air passages sprays of H_2O_2 and Blair's formula of benzoinal and resorcin.

The boy's physical condition previous to his first illness and up to recently had not been good. Tonics of cod-liver oil and of preparations of iron have materially increased the blood count, as the laboratory report shows. Daily care of the mouth and teeth with antiseptic gargles of H_2O_2 and formaldehyde in weak solutions are keeping the mucous membrane clean and healthy looking.

Prof. Henry Koplik's suggestion as to daily high enemas to clean and empty the colon have been carried out for the past six months, although patient had one relapse during this time. The flushing of the colon with salt solutions were done for the purpose of eliminating the factor of autoinfection as far as possible.

Dr. Koplik of New York saw the patient in his office as he was recovering from the fifth attack as described, and frankly said that he had never seen a case of erythema exudativum multiforme of the mucous membrane of this type. He thought a patient of his had a mild attack of a similar nature, but where the mucous membrane of the eyes, penis and rectum and anus were involved, and the severe relapsing condition, he had had no personal experience. He said, however, he would look into the matter on account of its clinical interest to him. Shortly after he wrote as follows: "I have been looking over the case you have allowed me to see and have come to the conclusion that my idea that you have a condition allied to urticaria as I first thought is correct and explains all the phenomena in your case. As I said when you were here, the literature is not so rare in cases of urticaria of the mucous membrane. The urticaria may begin on the mucous membrane. As a rule in the published cases it does and in a few days after the skin eruption follows. In your case the skin eruption is of the erythematous urticariformi type and in time bullæ are developed (urticaria bullosa). The eruption on the mucous membrane, nose, throat, tongue especially, it having been swollen, corresponds to what is known as urticaria of the mucous membrane. Again in one of these attacks the boy had pneumonia of a wandering type, and this is rather characteristic of many cases of this form of urticaria. Now,

how are the pseudo-membranous patches to be explained? They are to be explained on the ground of a mixed infection. The urticaria attacks the mucous membrane and in the severe form on the skin, vesicles or bullæ form as in aphthæ of the ordinary type. These vesicles burst and leave a raw exposed base, the streptococci of the mouth attack this exposed surface, and as in the aphthous stomatitis a pseudo-membrane is formed. So severe are some of these cases of urticaria of the mucous membranes that the reports say stenosis of the larynx through swelling of the tongue, epiglottis, and larynx was a principal feature. . . . I have analyzed this case because of its great rarity. . . . So far I have met many cases of urticaria of the mucous membranes in the literature, but none of the bullous or pemphigoid type."

Replying to Professor Koplik I said: "I note what you have to say of urticaria of the mucous membranes and of urticaria in general, but I cannot agree with you as to its being a case of urticaria. I believe we have here a case of erythema exudativum multiforme coming primarily, or in a freak manner, on the mucous membrane of the mouth and contiguous parts, and when the attack is severe, then we have the well-known skin eruption as described in the severe cases. Urticaria is diagnosticated by the wheals and the burning, stinging and itching and the absence of desquamation. The efflorescence of erythema exudativum is not evanescent, but persists throughout the disease, and for months afterward the copper-colored stains persist; the severe itching is missing and desquamation frequently takes place." Koplik in a subsequent communication inclined to the opinion that "as Kaposi says, both severe erythema may be combined with urticaria, and pathologically are of the same class, according to the experts on skin. As to urticaria involving the mucous membrane of the mouth, etc., Schwimmer,[3] who wrote the chapter in Ziemssen's Encyclopedia, says in rare cases it shows itself; the mucous membrane, as well as the common integument, were covered with an eruption of large wheals, which he called gigantic urticaria. He says, however, that he had no personal experience either with urticaria of the mucous membranes or of erythema exudativum multiforme of the mucous membrane.

Nothnagel[3] says, according to Kaposi, the occurrence of urticaria of the mucous membrane of the mouth and upper air passages is one extremely rare, and is also designated as giant urticaria, and frequently a glossitis takes place, mouth stained with blood and great embarrassment to speaking and swallowing.

Kaposi[4] and Milton[5] discuss this phase of it at length.

Nothnagel [6] also speaks of a stomatitis fibronasa et maculosa without reference to erythema exudativum multiforme, and quotes from Stoos, page 180, and says more likely the staphylococcus infection is implanted on the aphthous sores and raw places of the mucous membrane.

Unna[7] says we must at once separate from the pure angioneuroses of the skin certain well-defined dermatoses, which up to now have been considered with them: the true erythema exudativum multiforme of Hebra and erythema nodosum. These form a definite, most interesting group of infectious inflammations of the skin which, with certain angioneurotic symptoms, have certainly a superficial resemblance to the true angioneuroses. But in them there are, owing to the specific infectious irritant, histological changes in the texture of the skin which are absent in the simple angioneuroses.

Nothnagel, after giving a long list of causal conditions of membranous stomatitis, says cases will arise for which no reason can be assigned, especially the recurring and protracted forms may become very troublesome. With regard to the very unfavorable prognosis of the confluent type he had no personal experience.

Winfield[13] thinks that erythema iris is a rare form of erythema multiforme, and in rare cases the mucous membrane may be involved.

Unna[14] speaks of erythema exudativum multiforme of Hebra and herpes iris as breaking out occasionally on the mucous membrane of the mouth as well as the skin.

Pye Smith[15] says that all the skin diseases of the angioneurotic type have many things in common and cannot well be separated.

I have here brought together the different views of writers for the purpose of showing the various opinions held, and the confusion which apparently exists in the etiology and clinical picture of erythema exudativum multiforme.

During[8] says, "The complications which are liable to accompany or to precede erythema multiforme are varied, and are so diverse in kind that the subject may be best considered by referring to some recorded observations. In some of these cases, for the most part of a grave character, the nature of the disease may be said to be obscure. I believe that most of such cases should be looked upon as infectious. Thus occasionally disease of the respiratory and alimentary tracts, heart, kidney, and spleen, brain and cord occurs, due to the same influence that has produced the cutaneous affection. Such cases exemplify a general and not merely a cutaneous disease.

Leloir[9] reports a case in which twelve days after the beginning of an erythema exudativum multiforme, with bullous and hemorrhagic primary lesions, typhoid and profound adynamic symptoms set in. The autopsy disclosed marked pulmonary congestion, albumin in urine, and the microscope diplococci and streptococci in the blood and urine.

Whitehouse[10] says, "With reference to erythema multiforme, with or without the trunk being involved, analogous lesions may appear on the mucous membrane, notably those of the buccal and pharyngeal cavities. In these cases the lips are swollen and covered with vesicles or blood crusts. The mucous membrane of the cheeks, lips, and tongue present irregular raw-looking patches, outlined by the attached and ragged circumference of broken vesicles. The tongue may be greatly swollen, and the uvula and soft palate may also be implicated. In rarer cases the epiglottis and larynx are involved. The affection is extremely painful, rendering it almost impossible to open the mouth or to eat, and the decomposing tissues produce a characteristic fetor. In the only case I have seen in which the mouth was severely affected in this manner, the condition simulated more closely the mouth affected with pemphigus vulgaris than anything I am familiar with. In rare cases the disease may involve the vulvovaginal mucous membrane, the urethra and glans penis. Some cases have also been reported in which there were conjunctivitis and swelling with ecchymoses of the orbital connective tissues. As before stated, herpes iris generally occurs independently of other lesions of erythema multiforme, but exceptionally its lesions may be mingled with them."

I have quoted Whitehouse at length because he is the only authority that I can find that has stated

the clinical picture completely, as it applies to the case described in this paper. He makes no mention, however, of the pseudo-diphtheritic membrane, which sometimes attaches itself very firmly to the vesicles and raw places, due, as explained, to the pus germs present in the mouth. He also fails to mention the fact that this disease manifests a distinct disposition to relapse, as pointed out by During[11] and Lewin,[12] the latter authority having had a case that had suffered fifteen relapses. My patient had six attacks. Sometimes a year or two will be skipped, no apparent cause being discernible.

Dr. G. A. Blumer, formerly of the Bender Laboratory, kindly made for me last July a search of the Medical Index in the Surgeon-General's library while at Washington, and only noticed one paper which he thought had a bearing on the subject. It was an article contributed by Lanz[16] of Moscow, Russia, to the *Berliner klinische Wochenschrift*, entitled "A Case of Erythema Exudativum Multiforme, with Involvement of the Mucous Membrane of the Mouth and Pharynx." He reported an interesting case of his own and made an exhaustive review of all that had been written on the subject, and found only a limited number of cases, while a large number of authorities failed to speak of this subject. His patient was twenty-eight years old, who appeared at his clinic with a rash on his extremities, on the mucous membrane of lips, mouth, and glans penis. He gives then a minute differential diagnosis, and establishes that of erythema exudativum multiforme of Hebra. The eruption on the body was quite insignificant, while in my patient it covered about one-third of the body with large bullæ, freely secreting a serous fluid and in some places of a hemorrhagic nature. His patient was in hospital four weeks, and had no recurrence. Nine other cases of involvement of the mucous membrane in connection with the skin eruption are gathered from various sources, some showing the mouth complications only feebly, Lanz then says: "This review embraces about all the cases of erythema exudativum multiforme complicated with mucous membrane eruptions that the literature of recent times produces. In all of these cases the affection of the mucous membrane either started simultaneously with the eruption of the efflorescence on the skin, or after the skin exanthem was well developed." In contradistinction to this record, Lanz says his case is noteworthy in that the eruption of the mucous membrane preceded the skin lesions by at least three days. In my patient I wish to emphasize the fact that frequently the membranous stomatitis existed from four to ten days before the skin disturbance would manifest itself. The only case I can find which bears a close resemblance to the one of this paper is one reported by Fuchs in Lanz's contribution. This is the only case in which a membranous exudate is mentioned in connection with the papular eruption on the conjunctiva and the mucous membrane of the mouth. It is described by Fuchs as consisting of a thin, grayish white, quite firmly attached membrane on the conjunctiva and the mucous membrane of the oral cavity. With forceps the membrane could be pulled off in shreds from the conjunctiva, but left a bleeding surface, which in twelve hours would reform again. Like membranes covered the larger part of the mucous surfaces of the mouth, large, white patches covered the upper and lower lips and extended from the angles of the mouth along the inner border of the cheeks to the anterior palatine folds, besides large portions of the hard and soft palate, the uvula and the tongue were covered. Lanz calls attention to one more point of importance in his case, which was also very prominent in the one which I report. He calls it a peculiar condition, "eigenthümlicher." He says it is an accepted fact that the involution of the efflorescence of erythema multiforme is completed without scaling, or with only a slight amount. He quotes the high authorities of Neumann, Kaposi, Berend, and Schwimmer as holding these views. In fact, cases which show extensive desquamation must be exceedingly rare. In Fuchs' case the epidermis was lifted up in large strips, under which new epidermic cells were forming; in Lanz's case the epidermis on the hands was loosened in lamellæ (Desquamatio membranacea), while in other parts it was not so extensive. In my patient the peeling was severe in places, especially on abdomen, hands, feet, and in the face. Eight months after the severe attack the coppery discoloration of the skin and scarring marking the places of the original eruption are noticeable. In the face likewise the red blotches of new skin are apparent, especially if the boy exercises violently or is exposed to a low temperature.

THE HOSPITAL CAR; ITS EQUIPMENT, USES, AND IMPORTANCE.*

By WILLIAM W. SANFORD, M.D.,
NEW YORK.
CLINICAL ASSISTANT IN THE DEPARTMENT OF SURGERY AT VANDERBILT CLINIC AND BELLEVUE HOSPITAL SURGICAL CLINIC, COLLEGE OF PHYSICIANS AND SURGEONS DIVISION, NEW YORK CITY.

In the remarkable achievements of the medical profession, there seems yet an abundant opportunity for better surgical relief for those who must inevitably fall victims to railroad accidents, notwithstanding the many safeguards devised and put in operation by the most competent railroad managers.

In view of the wonderful results of mechanical ingenuity, in attaining speed, it is truly marvelous that such vast numbers of persons are safely carried each year by our railroads. It has been too well demonstrated in the West and South, during the past few weeks, however, that accidents do continually occur, often causing instant death, but more often resulting in injuries, which frequently, from lack of prompt application of remedial agencies, later prove fatal. It is especially to this class of the injured that the writer wishes to call attention, and also to those whose wounds invite sepsis so distressing in character at a later period.

Let me briefly describe first a car which is the result of a suggestion by President F. D. Underwood of the Erie Railroad, and secondly, a system of especially constructed and thoroughly equipped hospital cars, soon to be inaugurated along the entire length of this railroad.

When the plan was first proposed, both haste and

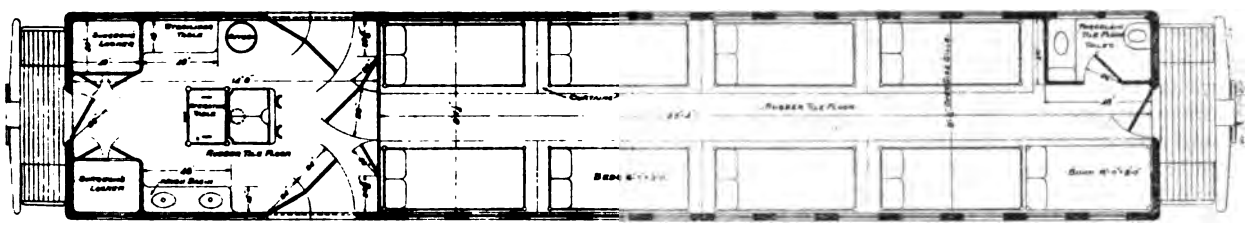
*Read at stated meeting of New York Academy of Medicine.

availability were necessary, and in consequence, a combination baggage and smoking car was selected from the regular passenger service. By the removal of the double row of seats, and all unnecessary fixtures, sufficient room was secured for the insertion of six ordinary hospital beds supplied with mattresses and rubber sheets. These beds were arranged lengthwise of the car. In the compartment formerly used for baggage, was placed an adjustable operating table, a case of surgical instruments, a small portable sterilizer, splints, stretchers, a cylinder of condensed oxygen, and a few drugs. The heating, lighting, and ventilation remained unchanged.

It is readily understood that such an equipment would be of great service, should necessity demand, although the crudeness of this car, and its very limited command of trackage must be apparent. Without several appropriately stationed hospital cars, distant portions of the road might suffer.

Every army, and indeed every regiment, every war vessel, every passenger steamship, and every city, is supplied with efficient means for immediate medical and surgical relief of all who are wounded, and almost daily reports prove that railroads should adopt measures whereby, in case of accident, every possible assistance may be given to the injured, and in the shortest possible time. To meet this demand this company has taken another step in advance, and resolved to establish a system of hospital cars, to be supplied with all necessary appliances to meet all emergencies.

The accompanying drawings will illustrate the efforts the writer has made in the arrangement of a newly and heavily constructed car, which will serve as a type of the several cars to be distributed at convenient distances along this entire road. This car will be fifty feet in length, of the usual width and height, and will be constructed in the strongest manner The interior arrangement will be as plain as possible, and all corners will be rounded. It will be finished in white, and as nearly dust-proof as possible. The floor will be of white rubber, in block form, of proper consistency, capable of adapting itself to the movements of the car while in motion, and of easy cleaning.



It will be divided into two compartments, a large one and a smaller one, 36 feet and 14 feet, respectively, separated by sliding glass doors of heavy frosted plate, through which a small stretcher of the wheel variety may pass. In the larger compartment which corresponds to a ward of a hospital, will be inserted eight stationary beds the frames of which will be of white enameled iron, arranged lengthwise. There will also be two beds suspended in such a manner that all jars of transportation shall be eliminated. Each of these beds will be supplied with a comfortable mattress, linen, rubber sheets, and blankets. From a rod, completely encircling each bed, will hang white curtains capable of enclosing such beds when desirable. Immediately at the outer end will be a toilet the flooring of which will be of white porcelain tiling. A swinging door will serve for admittance. Entrance to this ward will be by use of sliding doors, thus utilizing space formerly consumed by swinging doors.

In the smaller compartment, which corresponds to the accident, receiving, and operating room of a hospital, will be an adjustable operating table, a sterilizer for instruments, and, especially constructed for the limited space, cases for surgical instruments, for medical agents, and for previously sterilized and encased dressings. At one side will be two porcelain wash basins, with hot and cold water, managed by foot arrangement.

By day, light will be admitted from above by means of heavy frosted glass, while windows of the same material will be placed at the sides. By night, light will be secured by the use of electricity, a group of lights being placed in the center, directed from above, and aided by individual lights elsewhere. A patient may be admitted through sliding doors, on either side of the operating room.

This car is to be the type of the cars which will constitute the system of which mention has already been made. The importance of a *system* of such cars is manifest, when it is considered how inadequate is one such car to cover a line of several hundred or thousands of miles, with its many trains, increasing the possibilities of danger.

Each car will be cared for by a resident attendant, and inspected by a physician at stated intervals.

The possibilities of such a system of cars are far-reaching; for while these cars will chiefly perform the function of an ambulance, namely, for the better temporary treatment of the injured, and more comfortable transportation thereafter, yet they may also be used for the immediate operative procedures of a major or minor character in such emergency cases.

In this paper the writer would desire at this time to present especially the surgical possibilities of such cars, but he would not forget Dr. Beverley Robinson's valuable suggestion of the purely medical side, which involves many important considerations, and which may be hereafter separately considered.

It is proposed that such cars as described shall be stationed at accessible points, standing on a special track, so that they may be quickly despatched in charge of a train conductor, collecting en route the company surgeons and trained nurses who have been previously notified by telegraph.

By these means we shall have secured three things: (1) Saving of valuable time; (2) A sufficient number of competent physicians and nurses; (3) Equipment at hand.

Among the injuries sustained by passengers in derailments and collisions of trains, which demand prompt surgical treatment for the preservation of life, are serious crushing of extremities, involving the hard and soft parts, fractures of the skull, and grave trauma resulting in rupture and laceration of the contents of the abdominal and thoracic cavities. Should the checking of internal hemorrhage or the immediate repair of such viscera, or the transfusion of a saline solution be necessary, all of these may be performed with perfect safety and with satisfactory results.

The large percentage of deaths from injuries received in railroad accidents is doubtless due, in part, to the fact that the more seriously injured ones have died from the lack of immediate surgical or medical

attention, the result of the absence of facilities at hand, and the loss of time in transportation to places appropriate for treatment. Some may advise delayed operation for such conditions, while good authorities will insist upon prompt action.

The prevention of complicating conditions, immediate or remote, due to the nature of the injury, a better condition of the patient generally, and conveniences for such relief, are things to be considered in lowering the death rate, which is alarmingly great in these accidents. The removal of the possibilities of sepsis, which in a debilitated person has been, and may still be, prominent in the causation of mortality is also an important consideration. It may be safely said that there is not a physician or surgeon present, who does not believe that the need of establishing such a system of hospital cars upon our railroads is imperative, and it would seem to be the duty of railroad corporations to make such provision for the prompt relief of injured passengers.

As we recall the memory of the distressing railroad accidents of past years, the more impressed by the horrors of those recent occurrences in the West and South, it is a sad thought to picture the mangled and dying on beds of snow, or often in the dingy room of some wayside cabin, or, even as was recently the case, in a barn, being cared for by a chance physician, who, perhaps, himself only escaped total disability assisted by the willing laity, in his feeble efforts to alleviate the sufferings of the many injured, while miles away, after much delay, a relief train is being prepared as quickly as possible, but slowly and inadequately supplied with a few surgeons and possibly a nurse to be sent to the scene, hampered in their work by lack of facilities.

Allow the comparison with the immediate departure of a hospital car with its staff of a goodly number of surgeons and nurses, prepared for all emergencies.

It is well known that many of the greatest achievements that have been developed within your own recollections were at first looked upon with skepticism and opposed by men of influence, but after much dispute, they proved indispensable, and wonder is often expressed that such inventions were not long before in use.

While the future will doubtless witness the adoption of many new inventions which will add more safeguards to railroad travel, yet mechanism will sometimes fail at an inopportune moment, devastating storms will sometimes destroy a bridge just ahead of a train, a miscreant may wreck a train, or an employee will sometimes fail to obey an order; in consequence, human beings in large numbers will sometimes be killed or mangled.

The consideration of this matter, which these many years has been overlooked by so many railroad managers, cannot be too strongly urged by the medical profession, as a duty to the people who have so long suffered such great calamities with no adequate means of relief.

Variations of Weight During the Course of Scarlatina.—Garnier and Sabaréanu conclude from their investigations of this subject that the curve of weight during the course of scarlet fever may be divided into five periods. During the first days, the weight is stationary or increases more or less markedly. As soon as the fever declines, the weight decreases very rapidly for several kilograms. As long as the patient remains on a strictly milk diet, the weight remains stationary, having reached the minimum With increased feeding, a considerable increase occurs, and in a few days, the patient even goes beyond his original weight. Finally from the third week, the weight increases only slightly, or remains stationary.—*La Presse Médicale.*

THE PREVENTION OF DISEASE.

By JOHN B. HUBER, A.M., M.D.,
NEW YORK.
FELLOW OF THE NEW YORK ACADEMY, ETC.

During several summers past I have been inspecting the weekly parties which the New York Association for Improving the Condition of the Poor have been sending to the seashore. The main object of these inspections was the exclusion of cases of infectious disease. But besides this there was to me much else of professional interest. I should like to submit sundry data collected on these occasions.

Women and children made up the parties, and many of them, especially the infants, needed greatly the change from the air of the tenements to that of the sea. The eyes of these latter were sunken, their colorless faces had a clammy sweat upon them, their limbs hung flaccid, and they were listless and quite without the constant restlessness characteristic of healthy early childhood. Their appearance connoted the vitiated air, the poverty of sunshine, the pathogenic lack of cleanliness, and the dreadful summer heat in the crowded tenements of this city. To comprehend well the condition of these people one should examine some of the thousand odd photographs taken by our late tenement-house commission.

Many infants and children evidenced irregularity in feeding and overfeeding. The conditions which thus obtain will probably never be entirely corrected—crying and peevish infants, and solicitous mothers who know of no better way of pacification than the giving of the breast. Medical men have done much in the way of education here, but natural instincts have not thus been entirely overcome.

Many infants were very much overclothed—eight garments upon one infant; seven upon another of three months, "so as not to make a bundle." A weak infant of two months, whom the mother felt was gradually getting worse, enveloped in nine hot, moist garments. One mother had four children die of "bronchitis." Therefore she covered her baby's thorax heavily with woolen garments; so that it has no doubt since gone the way of the rest. Another had a reddened face and it puffed laboriously. The mother wanted to know why it had prickly heat. Its clothing was removed. There was a flannel binder, then two woolen garments, next a cotton shirt, and lastly a heavy woolen cloak. And so on.

Cases of neglected middle-ear disease were too often manifested; as were also enlarged tonsils, adenoids, retracted alæ, contracted chests with resulting oxygen starvation. These conditions, with swallowed excreta (often bacillus-laden) from the upper air-passages, mingled with unwholesome food and fluid, furnished ideal predispositions to tuberculosis.

In my earlier inspections many children were unvaccinated. Latterly most of them were vaccinated. However, the greatest number of unvaccinated children in one of last summer's inspections was thirteen among about 150 children—a proportion much too high.

In my earlier inspections I found granular lids in among 10 to 20 per cent. of the children. The change in this respect was, last summer, very marked. During Dr. Lederle's commissionership, a rigid examination of the eyes of school children was instituted. Very many cases were discovered by the medical school inspectors engaged by the Health Department. Toward the close of 1902 a "trachoma hospital" was instituted in the old Gouverneur Hospital, where, up to last Fall, under the excellent management of Dr. Herbert W. Wootton, more than five thousand operations were done upon children thus

afflicted, and where several times as many received treatment for lighter grades of the affection, with its kindred contagions (conjunctivitis).

My own personal observations during last summer may serve as some sort of index of the result of this "trachoma hospital's" work. In seven inspections, among a total of 1,048 children, there were 52 cases of trachoma. And of these 52, twenty-one were public school and kindergarten children, and 31 were parochial school children—a proportion which becomes greatly magnified when we consider the vast numerical preponderance of public school children over those in the parochial schools.

It was a pleasure to anticipate the benefit these poverty-stricken women must have received from the outings, which lasted from one to two weeks—women who had borne many children, who had chronic affections of various organs; old women going for convalescence after treatment or operation in hospital; or who were going to recuperate in order to undergo operation on their return. Many women regained thus the tidal strength of body which they had lost in the stress of the winter months, having been compelled to draw constantly upon the reserve force which should normally remain latent for emergency or unusual ordeals. Many of these women seemed indeed to be in the condition when the last straw would be fatal.

Among these women one much emaciated was married at sixteen, and her first child was born at seventeen; another was married at fourteen and had a child before her sixteenth year; a mother of twenty-six years had a child of twelve; one thirty-seven years old had had nine children; another of the same age had had eleven children, of whom eight had died; another, aged thirty-one, had had ten children; another at thirty-six, having nine children, had just come from giving birth to a tenth in a maternity hospital. Another had had eight children, but two of whom were living. She wept over "a beautiful baby, with lovely gold hair," that had died a few days after its birth. The other five had died at almost the same time of "diphtheria and scarlet fever, that had been brought into the house." This woman's dissatisfaction with the part allotted to her in the universal scheme was not because of the number of her children, which she had borne, but because they had been taken from her care.

One mother of seven children had to go out to work during the day—and showed it; there were tea-drinking mothers with weak spells, so that they felt "faint-like;" a mother who gave her baby the breast at night, but had to go out to do washing during the day; several manifested tuberculosis. One woman had put up a beautiful fight. She had been playing the game of life with an optimism most pleasing to contemplate. At thirty-six she was the mother of nine children. "Was she well," I had asked. "Sure," was her answer, with a grin and a trifingly impertinent wink, "only for that I couldn't stand the racket." Since then this heroine has died of consumption.

A while ago we were vouchsafed some strenuous expressions—as unquestionable as they were platitudinous—upon the subject of race suicide. When we consider the life-stratum here sketched we must conclude that the matter is not so simple of adjustment as might appear to the superficial observer. Would that the means for nurturing their families were commensurate with the affection these mothers bear their offspring.

As I look back upon these inspections I seem to have been contemplating a truly Hogarthean panorama. Old women, mothers and children passed by me successively: Old women, who could but guess how old they were, and who were suffering from rheumatism, asthma, heart-disease, and the like; a lame woman over seventy, whose leg had been broken in childhood; a child with hip disease, that had two abscesses draining away its strength; a child who was a cretin; another with scoliosis; an infant, thin, weazened, marasmic, that had the bottle given it "whenever it cried;" a child with "stomach trouble" that gripped a huge cracker and had its mouth filled to overflowing with half-masticated food, which was supplied it whenever it wanted something to eat; a child having its face disfigured with impetigo; a large family coming by themselves, their mother being sick in hospital; several members of a family all obviously hysterics; children aged two years still suckling, their mothers hoping thus to avoid pregnancy; a young woman with hysterical paralysis, which came on shortly after her marriage—with a Chinaman; a woman who could not remember if she had three or four children, and had to ask her mother to tell her; a woman who, to her great sorrow, had lost one among eleven children; an idiotic child who had become so after an attack of cerebrospinal meningitis; a child with facial paralysis, which came on as the result of a button having remained for months unsuspected in her nostril; a woman with exophthalmos, fast-beating heart, and an immense goiter; a woman who alone supported her family, her husband having an aneurysm, which must inevitably prove fatal; a mother with paralysis, consequent upon the birth of her child; a girl of twenty, nearly blind from measles, which she had contracted in childhood; an infant with an enormous hydrocephalus, certainly larger than a man's head; a boy paralyzed and imbecile since birth; a woman with hysterical deafness, which came upon her in an instant, and which is likely to leave her as suddenly; a woman whose whole left side had been burned, the cicatricial tissue being so tense that she could not bend forward; children choreic; with tuberculous vertebræ; two syphilitic infants whose father had had "blood-poisoning." A girl in her teens was hopelessly blind, and had been so since three days after birth; she had contracted an ophthalmia neonatorum from her uncleanly mother. An infant a few months old had a specific eruption distributed over its body. The father had been "burned, and the blood turned into blood-poisoning," so the mother assured me. Perhaps she believed this herself. Perhaps she was trying hard to make herself believe it. Here were a feminine subtlety for a de Balzac to dilate upon.

I sketch thus but one among many phases of life such as fall within the experience of all physicians. My purpose is to submit that lack of foresight and of education and unhygienic living were responsible for most of the conditions here touched upon—that most diseased conditions in general are preventable. Haply a fundamental tendency of modern medicine lies in the direction of prevention. Sanitation goes hand in hand with therapeutics and obviates the necessity for the latter whenever possible. And, in the cosmic range of its activities, it is the province of medicine far more than that of any other calling, to supersede the merely animal will-to-live with the optimist's *wille zum guten*.

44 East Sixty-fourth Street.

Appeal for New Cancer Hospital.—An appeal has been sent out by an organization concerned in the establishment of a hospital for women, for the purpose of affording relief to incurable cancer patients, and for the treatment, study, and prevention of cancer. The hospital will be situated in New York City, and will be known as the Fairhaven Sanatorium.

THE SYRIAN CLIMATES.

By HANNA MIKAIL RAHMI, M.D.,
BEIRUT, SYRIA.

This ancient land, decked with its monuments of antiquity, has different varieties of climate, varying from the Alpine to the littoral, from the stimulant to the sedative, and from a temperate to nearly a torrid one; yet all this variety of altitudes and weather is to be had within such a limited area, that in a few hours, or at the utmost a day, a person may go from one to the other with the minimum of expense. It seems that all European and American physicians lose sight of this fact, and omit to mention this beautiful land, having so many varieties of climates, in prescribing health resorts to tuberculous and other diseased persons in their textbooks on medicine.

The air of the land is wonderfully clear; its sun is amazingly brilliant; its invigorating and bracing sceneries are many and varied, yet in a very close proximity one to the other.

Its habits of life are widely different, having European civilization on one hand, the beautiful and hospitable customs of the Arabs on the other, with an admixture of the two between. The romance-inspiring mountains of Lebanon rise abruptly from the golden beaches of the ever-lashing Mediterranean, whose surface emits abundance of ozone that diffuses on the southwesterly slope of Lebanon.

Climates, from a medicinal standpoint, may be divided into: (1) Climates of altitudes: (*a*) Alpine climates, (*b*) sub-Alpine or intermediate climates. (2) Climates of plains: (*a*) inland climates, (*b*) marine climates.

Again, the climate may be divided with regard to the moisture of the atmosphere into: (*a*) stimulant, having a dry atmosphere; (*b*) sedative, having a moist air.

All the above divisions are found close one to the other beneath the sunny sky of Syria. As an insular health resort, the shore of Syria is excellent, being a sedative, especially to those ill with tuberculosis. In Beirut, the seeker finds a humid, mild climate, where snow never falls in the winter. The city has both kinds of life, the Syrian with its gentleness, tinged with modesty, and the European, followed by its train of pleasure and courtesies.

In Tripoli, a city to the north of Beirut, a mild Climate is found. The weather is like that of Beirut, with the exception that it is a little harder; the city is surrounded and filled with orchards of orange and its congeners. On the skirt of the city the land is covered with olive trees.

The stretch in breadth of the Syrian shore varies; in some places it is measured by yards, while the utmost breadth does not exceed six miles.

This littoral stretch of land merges into the mountains of Lebanon, a range of mountains running along the Mediterranean Sea. In Lebanon we get the climates of altitude; on the higher parts we find an Alpine climate, while the medium forms the sub-Alpine.

From Tripoli, with its insular climate, a person can reach Mt. Makmal, the highest peak of Lebanon and Syria, in about seven hours.

The mountain here is studded with villages, the hospitality of whose people is known; the land is verdant during the summer months, as it is abundantly irrigated with springs of fresh water. The historic cedars of Lebanon, which are in this spot, diffuse a balsamic scent of turpentine into the atmosphere.

Just below the cedars is the famous gorge of Kodesha, whose bottom is but little higher than the level of the sea. In the winter months no snow falls in this valley, while the perpendicularly towering Makmal is so heavily covered with snow that it is perpetual on its bald brow. In about two hours' walk, a person may reach the top from the floor of the vale, that is he climbs from an altitude but little above the sea-level to an altitude of about 10,000 feet, as the top of Makmal is over 10,000 feet above the sea-level. From Beirut a person may reach the top of Lebanon in a few hours, and so it is from any part of the shore.

The western aspect of Lebanon has a sedative, moist climate; its eastern flank is somewhat dry. Just at the eastern foot of Lebanon is Coele-Syria, a plateau between Lebanon and Anti-Lebanon. In this tableland, the inland plain climate is found. This plateau is about 4,000 feet above the sea-level; the air here is somewhat dry; the raised plateau is about ten miles in breadth and is quite long, appearing as a valley between the two mountain ranges. At its northern extremity this plateau gradually diffuses into the undulating plains of Hums and Hamah, which in turn widen out toward the Euphrates and the Syrian Desert. This tableland has many ancient ruins, the footprints of the ancient Egyptians, Chaldeans, Assyrians, Babylonians, Phœnicians, Khittes, etc. Bordering on this plateau is the parallel range of Anti-Lebanon. The air of Anti-Lebanon is dry, in some places it is exceedingly so. From this the ancient Damascus is soon reached. From Beirut all this range of variety of climates—Insular, sub-Alpine, Alpine, and Inland Plain Climate with the moist air of Lebanon and the dry air of Anti-Lebanon—may be reached in a few hours, a day to the utmost, by the train running between Beirut and Damascus. In short, Syria, especially that part about Lebanon, has a combination of climates so varied, yet so close to each other, such as exists nowhere else in the world.

A person may enjoy all the varieties of climates in one day, if he wishes, while in Syria.

Experiences with an Iodoform Mass for Filling Bone Cavities.—V. Mosetig-Moorhof reports the results of his experiences with a mass for filling cavities in bone following operations or destructive processes. This is made up of finely powdered iodoform (60 parts), spermaceti and oil of sesamum (20 parts of each), and the mixture is fluid at 50° C. The cavity in the bone about to be treated must be thoroughly cleaned and dry and the mass must be made to penetrate every portion. Drainage is then unnecessary, but if it is deemed essential, it can be best accomplished by narrow strips of rubber tissue. The filling subserves merely a temporary function, and it is either gradually displaced by the growth of new tissue and extruded from the wound, or where the latter has healed by primary union, it is slowly absorbed. As the process is a very slow one, symptoms of intoxication rarely appear, and the increase of pulse and temperature sometimes noted after the injection usually disappear by the third day. The procedure is well tolerated, and the author did not find it necessary to remove the mass in a single instance among a series of 220 cases. The cases most suitable for this method of treatment are those of chronic osteomyelitis of a circumscribed form, tuberculous osteomyelitis and the acute variety with necrosis. In joints it is essential to eradicate all diseased tissues, including the synovial membranes and all involved parts of the capsule and the ligaments, the question of resection being limited as much as possible. The author gives in detail the histories of 195 cases in which the method was used, in some of them a number of times, and closes with the remark that in no instance was the treatment unsuccessful.—*Deutsche Zeitschrift für Chirurgie*, Vol. 71, No. 5.

THE PHYSIOLOGY OF SIMULTANEOUS AMBIDEXTRAL WORK.

THE late Charles Reade, in the opinion of many the greatest writer of fiction that England has ever produced, was like most men of genius addicted to what ordinary persons called fads. He was in the habit of occasionally airing in the lay journals views with which the every-day individual was not in agreement, in many instances doubtless due to the fact that these opinions were beyond the comprehension of some readers and were looked upon as visionary by others. Among the various subjects in which this great writer interested himself, was that of ambidexterity, and he lost no opportunity of circulating his theories regarding this matter. Read was convinced of the benefit that would result to the individual and the community if the human race could use right and left hand with equal facility and skill.

A lecture was delivered recently in England before the Ambidextral Culture Society by its secretary, Wm. John Jackson, abstracts of which were published in the *Hospital*, March 26. The principles which it is the object of the Society to maintain are: (1) that it is possible to do two things well at the same time, and that every ordinarily intelligent person is capable of becoming an expert in the performance of two concurrent and unrelated acts as he can be in the separate accomplishment of one. (2) That the acts which are thus designated as concurrent or simultaneous are, so far as the senses can determine, absolutely so whatever the refinement of analysis and science may ultimately declare them to be. For all practical purposes they occur precisely at the same instant, though they may be theoretically nothing more than inconceivably rapid alternations of volition. (3) That a certain amount of simultaneous work, under specified conditions, is healthy and expedient. (4) That under other particular conditions, it is necessary and harmless. (5) That whilst it is both proper and advantageous to prepare and qualify children for the execution of two-handed work, and more especially of two-handed writing during their school life, it would be unwise if not pernicious to encourage or prescribe for artizans and others the least amount of simultaneous manual labor, over and above what has hitherto been found requisite for the effective execution of the work to be done in the several industries of manufacturing life.

Dr. A. L. Wigan, in his monograph on "The Duality of the Mind," published sixty years ago, puts forward the following among his twenty propositions: (1) That each cerebrum is a distinct and perfect whole as an organ of thought. (2) That a separate and distinct process of thinking or ratiocination may be carried on in each cerebrum simultaneously. (3) That each cerebrum is capable of a distinct and separate volition, and that there are very often opposing volitions. . . . (20) That every man is, in his own person, conscious of two volitions, quite distinct from the government of the passions by the intellect; a consciousness so universal that it enters into all figurative language on the moral feelings and sentiments, has enlisted into the service of every religion, and forms the basis of some of them—as the Manichean.

Brown-Sequard, in reference to the same question, says: "We have a great many motor elements in our brain which we neglect absolutely to educate. Such is the case particularly with the elements, which serve for the movement of the left hand. Perhaps fathers and mothers will be more ready to develop the natural powers of the left hand of the child, giving it thereby two powerful hands, if they believe as I do, that the condition of the brain and spinal cord would improve if all their motor and sensitive elements were fully exercised." There are many instances which can be cited of concurrent mental processes. "With regard to the question," says the *Hospital*, "of whether the volitional impulses which govern the processes performed simultaneously by the two hands are really themselves simultaneous, or whether the "inconceivably" rapid alternation theory is correct, it is impossible to say, but the proposition is a correct one that these transmissions of will are progressing concurrently from two totally different and independent agencies, each of which is equal to its confrère in every particular, so far as reason and the closest observation can discover.

It is the aim and purpose of the Society to insure that every child at school shall be so drilled in both separate and simultaneous use of his two hands that whatever line of life he may enter, he will be fully prepared with two perfectly developed hands, equally sensitive, equally strong and equally skilful.

There would seem to be no valid reason that the left hand should, at any rate, be put to far greater use than is at present the case. The comparative lack of skill in the left hand is frequently a source of discomfort and even of loss to the individual. An objection brought against the person who possesses a trained and skilful left hand is that according to statistics gathered by Lombrosol, these qualities are very often observed in criminals. It is true that to the left hand has been attached somewhat of a slur, it is not considered so honorable as the right hand. Indeed the Latin name for left hand, sinister, has a place in the English language, and a meaning the reverse of complimentary. However, all this is a matter of tradition, and it could not be but to the advantage of the human race if the left hand was so trained that it might be used with much more skill and facility than is at present the case.

LATENT TUBERCULOSIS.

IN a recent symposium before the New York Academy of Medicine, various modes of infection in tuberculosis were set forth. The periods of infancy and childhood were particularly referred to. Infection by inhalation, at least as regards the involvement of the cervical glands and those of the upper air pas

sages and the bronchi, was generally agreed upon. Ingestion infection was dwelt upon, especially by Ravenel of Philadelphia; and here there was also general agreement, although unanimous opinion was not so nearly approximated. In the discussion Dr. Dowd emphasized in very scientific terms the comparative frequency of infection through wounded tissues. The relative proportion of these various modes was left undetermined.

Two considerations occur to one. In the first place there is the thesis maintained by von Behring, that infants very early ingest bacillus-laden milk and other foodstuffs. His opinion is not to be set aside merely because upon autopsy in children the tissues intimately related to the alimentary tract do not generally evidence tuberculosis. For the point of entry is by no means always the focus of the initial tuberculous process.

Ravenel has demonstrated the tubercle bacillus in the chyle of animals that were fed upon bacillus-laden material. And he and many others very cogently argue that the bacillus may pass in the lacteals from the digestive tract to the thoracic duct, thence to the vena cava, the right heart, and so to the pulmonary parenchyma; so that the initial tubercle in and about the lung vesicle may thus result from ingestion rather than from inhalation infection.

In children, moreover, caries, "white swellings," hip disease, and like lesions evidence tuberculous foci, to which, in at least a large proportion of cases, bacilli have been carried by lymph and blood channels, from remote points of entry, in the digestive tract, wounds, or even, for that matter, through unbroken skin and mucous membranes.

In the second place we note that deaths from tuberculosis are comparatively rare before the fifteenth year. Moreover, before that year pulmonary tuberculosis is very rare indeed. From adolescence to the forty-fifth year every third or fourth adult, in the vast majority of cases, dies of tuberculosis of the lungs. When we consider that infants and children are certainly as much—perhaps more—exposed than adults to tuberculous infection, we must infer that there is a period of latency in this disease, that in many cases the infection must have lain dormant through the earlier years of life, until tuberculous formation has been induced by the advent of some acute, exciting cause.

It may not be *mal apropos* to draw here an analogy between this disease and syphilis. Of course we have here two distinct pathological entities; yet there are not a few points in common, and perhaps there will be more when we have discovered the microorganism which is responsible for syphilis.

When either of the parents is syphilitic the child may manifest the disease at birth; or it may exhibit characteristic lesions within a few weeks; or the specific infection may remain latent and may not show itself until after the fifteenth or twentieth year. In the play *Ghosts* there is set forth in a most gruesome manner the symptomatology of a cerebral gumma in the son of a roué, a young man in whose previous life no specific manifestations had appeared. It may seem poor science to cite as an example a character portrayed for the stage. However, it is said that Ibsen consulted an expert in syphilology for his basal facts; and no medical man will question the ghastly reality of the picture.

Tuberculosis differs radically from syphilis in so far as it seems well settled that in a vast majority of cases it is not tuberculosis itself, but a tendency to this disease, which is transmitted. This vulnerability is exhibited in the scrofulous temperament, and undoubtedly the bacillus engrafts itself with peculiar ease upon strumous tissues. However, even in children born healthy there is no difficulty, as von Behring and others appear to have demonstrated about the reception of the Koch bacillus within the organism. The point here is with regard to the latency of tuberculosis. Here an analogy with syphilis seems complete—that the tubercle bacillus may remain for years inactive in some perhaps remote portion of the organism (a lymphatic gland, the bone marrow, or a joint) until a traumatism, an aberration of adolescence, or some other acute cause may provoke it to pernicious activity.

Campaign against Yellow Fever in Mexico.

In Public Health Reports, March 11, 1904, is published a report by Dr. E. Liceaga, President of the Superior Board of Health in Mexico, of the campaign against yellow fever to be undertaken in that country. The plan of crusade against the disease is founded upon the fact that the stegomyia fasciata mosquito is the principal, if not the only, means of transmitting yellow fever. The methods proposed to be put into practice to prevent the development and propagation of yellow fever are: The isolation of the patient, the destruction of the infected mosquito, and the prevention of the development of fresh mosquitos of the above-mentioned genus. Isolation in Mexico is to be rendered as effective as possible. First, by the obligation, which lies on all physicians under the sanitary code of the United Mexican States, of notifying the sanitary authorities of all patients who are suspected of having yellow fever. Second, by the obligation, which is also legal on all heads of families, chiefs of workshops, colleges, schools, barracks, etc., to give similar notice. Furthermore, strict and continued domiciliary visits have been provided for. The isolation of patients in yellow-fever epidemics in Mexico is absolutely obligatory.

The destruction of infected mosquitos, and the larvæ of the stegomyia fasciata, is to be carried out in the most effective manner.

In order to prevent the spread of the disease from an infected to a healthful locality, no suspected or sick person is to be permitted to leave an infected locality for a fresh one until he or she has been examined by a physician. Should the investigation show that the person who desires to depart is not sick, a passport will be granted stating name, age, sex, and profession, also stating that such an individual was in good health and not suffering from any feverish symptoms at the time when the inspection was made, and destination. The medical committee will keep a register showing all these data, and will duly advise the political and sanitary authorities, if there are any, of the place to which the passenger is traveling. The person traveling under passport will be bound to present it at the sanitary stations through which he may pass and at the termination of his journey, so that he may be under surveillance for five days. Railway carriages or ordinary coaches, or any kind of vehicle will be disinfected before they are allowed to depart, and this disinfection will be continued at every sanitary station. In fact, the object will be to destroy infected mosquitos by every possible means.

The sanitary stations, which it is proposed to establish in suitable localities, are intended to ex-

ercise a vigilance over the passengers who travel by railroad, coach, on horseback, or on foot, and the detention therein of the passengers who are either sick, or suspected of being so, are sufficiently efficient when well established. "This was proved," says Dr. Liceaga, "by the results that were obtained in the State of Sinaloa when the port of Mazatlan and neighboring villages were invaded by bubonic plague."

The scheme suggested by the Superior Board of Health of Mexico to stay the spread of yellow fever appears to be thorough, and when put into practice should have the desired result.

Treatment of Cancer with Radium Bromid.

Mr. H. G. Plimmer of the Lister Institute of Preventive Medicine relates, in the *Lancet* of April 16, the results of experiments carried out by him, with radium bromid on seventeen cases of cancer at the Cancer Hospital, London. The amount of radium used for these cases was 30 milligrams. The cases made the subjects of experiment consisted entirely of carcinoma, many of them being in a very advanced condition. The individual exposures varied from forty minutes to five minutes, and the capsule containing the radium was placed directly on the nodules or lumps, the only thing intervening between the radium and the skin being the talc top of the capsule. The cases were left for a month after the exposures and then examined. The effects in all the cases were negative, either no change or an increase in the size of the nodules. The effect on the skin varied in the different cases; an exposure of ten minutes was generally sufficient to produce blistering, and then scabbing, and under the scabs there was found a very slowly-healing ulcerated surface. The radium had apparently no effect with regard either to causing or relieving pain, and the irritation of the blisters was slight. From three of the above patients who died some of the nodules which had been treated were excised and subjected to a careful microscopical examination. In all these cases no change was found either in the cancer cells or in the fibrous tissue and none were degenerated. There appeared to be an increase in the amount of the subcutaneous round-celled exudation which was greater in amount in those nodules which had been more recently treated, but the irritation of the skin would sufficiently account for this. Dr. Apolant, writing from Professor Ehrlich's laboratory, records, in a recent number of the *Deutsche mediginische Wochenschrift*, some very satisfactory and striking results obtained by treating very rapidly growing nodules of inoculated cancer in mice. Professor Exner in Vienna arrived at similar results in a case of melanotic sarcoma with multiple rapidly growing nodules in the skin. Mr. Plimmer says "it appears as if the emanation from radium can only act upon young and rapidly growing cells, and that older cells, especially if surrounded by fibrous tissue, are less and less easily affected, and if there be an excess of fibrous tissue the cells are not at all affected."

Hypnotism in the Treatment of Chronic Alcoholism.

Hypnotism has been used for some time now in the treatment of confirmed inebriates. Those who have had experience of this form of treatment report satisfactory results. Dr. Milne Bramwell, in his recent work on hypnotism, states that he has treated during the past twelve years seventy-six cases of chronic alcoholism by hypnotic suggestion, and has obtained the following results: cured, twenty-eight; much benefited, thirty-six; unaffected, twelve. Some of the best results have been with women, a contradiction of the popular theory that women are incurable. Dr. Creed of Sydney, N. S. W., has recently drawn up a report on drunkenness and its prevention and treatment in that colony. He insists upon the virtue of hypnotic treatment, and urges that the treatment should be tried in the public institutes of the colony, as well as in private practice, and he is confident it will be found to cure a large proportion of drunkards.

Dr. Chas. Lloyd Tuckey, writing in the *British Journal of Inebriety*, April, gives the following as his conclusions reached by a close study of the matter: (1) Most alcoholics are good hypnotic subjects. (2) To insure reasonable prospect of success, the patient should have a real wish to be cured, and should be placed under favorable conditions while undergoing treatment. (3) He should be kept under observation for at least a year, during which time he should feel himself on probation. In the opinion of Dr. Tuckey the treatment has these advantages: (1) It is rapid in action. After two or three sittings there is generally a marked improvement in the patient's general mental and moral condition. (2) The patient is able to continue his business, and is thus saved the expense and loss incurred by confinement in a retreat. Domestic ties are not broken, and the demoralization which often results from the enforced idleness and evil companionship, almost inseparable from life in a retreat, is avoided. Suggestion should aim at two objects—absence of craving and even physical repulsion toward alcohol, and increase of power of resistance and restoration of self-control.

Tropical Sanitation of Ships.

Mr. A. J. Evans writes in the *British Journal of State Medicine* on this subject. The writer discusses the matter from the standpoint of personal experience, as for some years he has been a medical officer on steamers employed in the West-African coasting trade. The chief of the diseases which attack the passengers and crew of a coasting steamer within the torrid zone is, it need hardly be said, malarial fever. Therefore, the first thing to be done in order to rid a ship of malara, is to rid it of mosquitos. The measures to be taken to bring about this result are the use of nets and fumigation. The owners and captains of coasting steamers are not as a rule willing to incur expense for the sake of their crews, and thus precautionary methods against mosquitos are not generally put into practice. The writer points out that this unwillingness to expend money for the purpose of keeping the crew in good health is a short-sighted policy, and by no means economical in the long run. He advises owners of coasting vessels in tropical climates to give their captains directions to use every effort to keep the crews free from malarial infection. The next step is to make the sailor himself realize the way malaria is transmitted. This is likewise a hard task, as the ordinary seaman is both careless and ignorant, and not likely to be easily persuaded that malaria is spread by the mosquito. Mr. Evans has adopted the plan of endeavoring to impress the fact upon the mind of the sailor, by means of a printed pamphlet setting forth in plain language how malaria is conveyed, and the methods which ought to be taken against contagion. This pamphlet is posted up in a conspicuous part of the ship, so that all can read it. The next point of importance is the prevention of infection while on shore. The writer is of the opinion that a large percentage of the cases of malaria on board ship are contracted by allowing sailors ashore after sundown, when the mosquito is most active.

Lastly, the administration of quinine as a prophylactic in malaria is discussed. Mr. Evans states that a week before arriving at a malarious district the administration of quinine should begin, in order that the system should be saturated with the drug before infection can possibly occur. This should be continued at regular intervals, while in a malarial locality and for at least two weeks after leaving it. The latter point is the one generally overlooked on board ship; it has been usual to take quinine only while lying in a malarial port, and on leaving it to discontinue its use at once.

The other diseases to which those who ply along the coasts in the Tropics are subject are smallpox, yellow fever, and sunstroke. The precautions to be taken against the first-named disease are obvious. Every member of the crew should have been recently vaccinated, and steps should be taken to ascertain this before he is allowed to sign articles. Every care, too, should be taken when embarking black passengers on the coast, that they are in a healthy state; another point of importance is that the vaccine lymph should be renewed every voyage, and that it should be specially stored in a cool place, in order to prolong its efficiency. With regard to prevention of yellow fever, similar efforts to exclude mosquitos, as practised in preventing malaria, should be made.

As to preventing sunstroke, captains of coasting vessels in the tropics should provide their crew with suitable headgear when exposed to the sun, and the men should avoid as much as possible extreme fatigue. In conclusion the writer urges upon shipbuilders the need of turning their attention a little more to the accomodation of the crew in tropical climates. Arrangements in the forecastle appear to be much the same, whether the ship is intended for the tropics or arctic regions. Furthermore, proper hospital accommodation should be provided for at least 10 per cent. of the crew carried.

News of the Week.

New Fordham Hospital.—Plans for the group of new Fordham Hospital buildings to be erected by the city of New York at Crotona avenue and the Southern Boulevard were filed on April 28 at the Building Department. The structures will include the main hospital building, five stories in height and standing on a plot 305 by 43 feet, a four-story power house, which will also contain a laundry and servants quarters; a two-story brick stable and morgue, and a five-story nurses' home. The total estimated cost of these buildings is $560,315, of which $339,000 will be spent for the hospital itself, $129,000 for the power house, $52,315 for the stable and morgue, and $40,000 for the nurses' quarters.

Harbin Most Insanitary.—According to the *New York Times*, a despatch from Harbin, recently received, gives a striking account of the horrible condition of the streets and the entire absence of sanitary arrangements in that town. There is no municipal administration, and the Russian authorities have forgotten to pave the streets, organize a corps of scavengers, or make drains. All these requirements have been left to chance, and now the authorities have been overtaken by the war. Thus Harbin, which was visited by cholera two years ago, and which suffers from typhus every summer, will probably be the scene of an outbreak of plague this year. The wounded are brought from the South to be cared for at Harbin, and out of the enormous sums collected in Russia for their benefit, a large amount must be set aside for sweeping, cleaning, and disinfecting the town in order to render it a tolerable place of residence, as otherwise it cannot, during the summer months, be anything but a center of contagion.

Big Influx of Immigrants.—The second largest number of immigrants that ever arrived at New York port on one vessel came on April 27 on the steamship *Neckar*, from Naples. Besides the 11[illegible] persons in the cabin, there were 2,497 other passengers aboard her. During the same day 8,478 passengers were landed from twelve steamships.

Measles Very Prevalent in Greater New York.—According to the Health Department figures, measles is spreading in Greater New York. The report for the week ended April 23 showed 1,630 cases in the five boroughs, with 37 deaths from measles and 13[illegible] from bronchopneumonia following measles.

Crusade against Impure Candy.—A crusade against the manufacturers and sellers of impure candy is about to be inaugurated by the New York State Agricultural Department. Special agents have discovered that a considerable amount of impure candy is being sold throughout the State.

Legacy for Tulane Medical College.—By a recent decision of the Louisiana State Supreme Court Tulane Medical College receives the bulk of the estate of the late A. C. Hutchinson, President of the Louisiana and Texas Road.

To Get Rid of the Mosquito.—Representative Scudder introduced, on April 28, into the National House of Representatives a bill to create a commission to investigate the question of redemption of swamps and marshes in New York and New Jersey with a view to improving sanitary conditions and exterminating the anopheles mosquito. The measure provides that the commission shall be appointed by the President and serve without compensation.

Strange Ruling of a Sandusky Judge.—In Common Pleas Court Judge Reed ruled that the Ohio State medical registration and examination law is unconstitutional because it limits the right to practise the healing art without the use of drugs or medicines to osteopathy, and by the rule of exclusion Christian Scientists are prohibited from practising such pursuits. He said it should be amended so as to allow for a reasonable examination for Christian Scientists and for their registration. The ruling was made in the case of Oliver W. Marble of Sandusky, who was convicted some months ago and fined on a charge of practising medicine without license. Marble had treated a case of rheumatism according to Christian Science.

Salaried Resident Surgeon.—The Mount Sinai Hospital will appoint a salaried resident surgeon for its private pavilion. Applications will only be considered from those who are graduates of a hospital.

Tri-State Medical Association of the Carolinas and Virginia.—The Tri-State Medical Association of the Carolinas and Virginia met at Danville, Va., February 23 and 24, 1904, when the following officers were elected: *President*, Dr. W. L. Robinson, Danville, Va.; *Vice-Presidents*, Dr. G. DeFoix Wilson, Spartanburg; Dr. H. A. Royster, Raleigh, N. C.; Dr. Southgate Leigh, Norfolk, Va.; *Secretary and Treasurer*, Dr. Rolfe E. Hughes, Laurens, S. C.

Association of American Physicians.—The Nineteenth annual meeting of the Association of American Physicians will be held in the New Willard Hotel, corner Pennsylvania Avenue and Fourteenth Street, Washington, D. C., on May 10 and 11, 1904.

Florida Medical Association.—At its last annual meeting, held at Live Oak, the Florida Medical

Association amended its constitution, making Jacksonville the permanent meeting place of that body. Dr. E. N. Liell of Jacksonville was elected president for the ensuing year.

Peoria County Medical Society Endorses Pure Food Bill.—This society, at its last meeting, adopted resolutions favoring the adoption of the Hepburn Pure Food Bill.

Reëlection of Dr. Hurty.—Dr. John N. Hurty of Indianapolis has been unanimously reëlected secretary of the Indiana State Board of Health for a term of four years.

Ohio State Hospital for Consumptives.—The House passed and made a law the Senate bill by Heinlein providing for a commission to select and purchase a site and erect a State sanatorium for the care of incipient pulmonary tuberculosis. The bill carries an appropriation for the purchase of a site. The hospital will cost about $175,000 more. About 1,000 persons will be treated per year.

Cincinnati Doctors Promoted.—Dr. J. H. Landis has been elected to the chair of general medicine, and Dr. Tilmore has been elected pathologist at the Betts street hospital. Dr. Park Gilmore has been promoted from interne to the chair of pathology and microscopy at that institution.

Internes for Cincinnati Institutions.—The following young physicians from the Ohio Medical college have won interneships at the Good Samaritan Hospital: Dr. Harry Stuntz, Dr. George Sikes, Dr. J. E. Rogers, and Dr. Elbert Weaver, a brother of Coroner Weaver. The alternates are: Dr. Charles Hancock, a brother of Professor Hancock of the University, and Dr. Hubert Ellis of Oklahoma Territory. The interneships at the German Deaconess Hospital were won by Dr. W. R. Martindill of the Ohio College and Dr. Cunningham of the Miami Medical College. Drs. Barker, Heisel, and Southworth have been selected as internes at the Jewish Hospital, and Dr. Fannie S. Hollingshead at Christ Hospital. Dr. J. E. Heap and Dr. H. A. Zimmerman have been selected as outdoor obstetric internes at the Ohio Medical College.

Internes for Cook County (Ill.) Hospital.—Of the new internes for this institution, eight are graduates of Rush Medical College, four of Northwestern University Medical School, and one of the College of Physicians and Surgeons.

Promotion of Dr. Richings.—Major Henry Richings, Rockford, Ill., surgeon Third Infantry, Illinois National Guard, has been appointed assistant surgeon-general, and chief surgeon of the Third Brigade, with rank of lieutenant-colonel.

Bazaar to Aid Chicago Hospital.—The people of South Chicago are preparing to establish in the center of that district a permanent home for the South Chicago Hospital of sufficient capacity to meet the demands of that part of the city. With that object in view, the directors announce a two weeks' bazaar for the purpose of starting a permanent hospital fund. It is the intention to replace the present small and inadequate institution with a hospital building involving the expenditure of $100,000.

American Medical Editors' Association.—The annual meeting of the American Medical Editors' Association will be held on June 6, at 2 P.M., at Dennis Hotel, Atlantic City, N. J.

Contagions Sent to Cincinnati.—It is charged that certain railroad camps in Southern Indiana are making a practice of sending cases of contagious disease to Cincinnati, where it is necessary to care for them in the Public hospitals. Health Officer Clark W. Davis will bring the matter to the attention of the State Board of Health with the request that it have the Indiana Board put a stop to the practice.

Cincinnati's Pneumonia Death Rate.—The statistics at the City Hospital show that the death rate from pneumonia this spring has exceeded 75 per cent.

New York School of Clinical Medicine.—At the meeting of the Medical Board of the New York School of Clinical Medicine, held April 9, Dr. J. L. Adams was elected secretary of the school, and professorial and other distinctions were conferred upon the following in the departments specified: *Mental Diseases:* Professor, E. C. Dent, Superintendent Manhattan State Hospital West, Ward's Island. *Internal Medicine:* Professor, Wm. Brewster Clark, M.D. *Gastrointestinal Diseases:* Professor, Robert Coleman Kemp, M.D. Associate Professor, Graham Rogers, M.D. *Hydrotherapeutics:* Professor, Alfred W. Gardner, M.D. *Ophthalmology and Otology:* Professor, Geo. Ash Taylor, M.D. Clinical Instructor and Assistant, Wm. E. West, M.D. *Genitourinary Diseases:* Chief of Clinic and Associate Professor, C. Stern, M.D. *Dermatology:* Chief of Clinic and Instructor, L. D. Weiss, M.D.

State Board of Medical Examiners.—The examinations of the State Board of Medical Examiners of New Jersey will be held at Trenton, N. J., June 21 and 22. Application for the regular blanks should be made before June 11.

Citizens Object to Erection of a New Chicago Hospital for Infectious Diseases at Proposed Site.—A meeting was recently held by the owners of property in the vicinity of the proposed site of the Memorial Hospital for the Treatment of Infectious Diseases, and the trustees decided to call a public meeting of all persons interested in any way in the project. Dr. Billings explained the great need of such an institution in Chicago, and gave a brief outline of what are known as infectious diseases, their effects, and the best methods of treatment. He said there is no possibility of contagion from a properly conducted hospital. There is to-day in Chicago only one place where infectious diseases can be treated, and that is in the addition to the Cook County Hospital. No institution more beneficial to the public of the city of Chicago has been recently proposed. The aim is to treat certain infectious diseases, such as measles, diphtheria, and scarlet fever, in a scientific manner. This hospital is to be established on a purely philanthropic basis at the place where such diseases can be treated and studied from a scientific standpoint, in order that the germs of the disease may be located and proper means be determined upon for its extermination.

Scarlet Fever in Evanston, Ill.—This city has seventeen cases of this disease under quarantine at present, most of the patients being children who attend the Dewey School.

Chicago Eye, Ear, Nose, and Throat College.—At a recent meeting of the stockholders of the Chicago Eye, Ear, Nose, and Throat College, the following officers and directors were elected: Drs. Wm. A. Fischer, Adolphus G. Whippern, H. W. Woodruff, Thomas Faith, and John R. Hoffman. The directors thereupon elected the following officers: *President and Treasurer*, Dr. Wm. A. Fischer; *Vice-President*, Dr. Adolphus G. Whippern; *Secretary*, Dr. John R. Hoffman.

Rejection of Chicago Inspection Plan.—Some time ago Mr. Hartung, trustee of the Board of Education, made a plea for a more rigid examination of

school children; but the school management committee of the board has rejected the plan.

Physician Accused of Performing an Illegal Operation.—Annie Fitzgerald, a servant girl employed at the Harlem Hospital, died at that institution on April 29, apparently from the effects of a criminal operation. An hour before her death she made an ante-mortem statement to Coroner Jackson, declaring that a physician associated with the hospital was responsible for her condition, and that he had performed the operation. She refused, however, to tell the name of the doctor. At the hospital it was denied emphatically that any operation had been performed there upon the girl.

To Restrict the Spread of Tuberculosis.—The Philadelphia Bureau of Health, in its crusade against pulmonary tuberculosis, has arranged to disinfect all unoccupied houses on the request of prospective tenants. The work will be done at the expense of the city, providing the renter will agree to clean the building thoroughly before moving in. By this means it is hoped a prolific means for the spread of the disease, especially among the poor, will be removed.

The Mayor of New York Vetoes Coroner's Bill.—Mayor McClellan has returned to the Governor of New York State with a veto message the bill abolishing the office of Coroner.

Tenement Law of New York State Changed.—An amendment to the labor law of New York State has been signed by the Governor. This amendment transfers from the Factory Inspector to the Commissioner of Labor jurisdiction over tenement-house factories. It provides that no license for such factories may be issued while there exists in the tenement in question any communicable disease, or any violation of the local health ordinances indicating any insanitary condition.

Dr. Ignatius Friedman, a prominent physician of Cleveland, Ohio, was killed this week in a collison between his carriage and a street car.

Race Suicide in Great Britain.—According to the New York *Sun*, of May 1, the ontroversy which has cropped up in Great Britain at intervals during the past few years has received a fresh impetus from a speech recently delivered, in which the speaker denounced fashionable marriages in which the duties of life were shirked and marriage made a mockery as being more terrible than irregular alliances unsanctioned by the church. The Bishop's outspoken address has given rise to a widespread controversy. Mr. Henry James, the American novelist, who lives in England, disagrees with the Bishop as to the evil effects of a falling birth rate. He thinks that it only shows that people are beginning to think for themselves, and that it is the ultimate satisfactory solution of all social troubles and labor difficulties. Large families are an inexpressible burden to the working classes, and the over-stocked labor market leads to poverty, degeneracy, and crime. With foreign invasion stopped and large families abolished, England will have ten times a happier population and greater individual health. The discussion on the matter proceeds apace, many persons taking the Bishop's view of the question while others support that of Mr. James.

Exhibit of Mosquitos at the St. Louis Fair.—Dr. Frederico Torralbas, a member of the Havana Supreme Board of Health, will exhibit a large number of mosquitos which he has brought from Cuba, for the purpose of illustrating the theory of the transmission of the yellow-fever germs. Dr. Torralbas will also erect a series of tents at St. Louis, provided with wire screens, the same as were used when the American and Cuban surgeons made a series of experiments to show that yellow-fever germs can only be propagated by mosquitos biting human beings. Men will be employed for a practical demonstration.

Falling Off in Immigration.—The total number of immigrants for the month of April who arrived at the port of New York was 70,000. In April of last year the number was 101,000.

Anthropometric and Psychological Exhibits at the St. Louis Exposition.—Dr. R. S. Woodworth of Columbia University has been appointed to go to St. Louis this month to take charge of the anthropometric and psychological exhibits at the St. Louis Exposition. He will be assisted by F. Brunner, also of Columbia, who is now in St. Louis arranging the different apparatus required by Dr. Woodworth in the series of experiments he intends to make.

Cincinnati Chapter of Un Sigma Nu.—The fraternity of medical men held a banquet at the Grand Hotel, Saturday evening.

Obituary Notes.—Dr. JAMES S. STEVENS died in Philadelphia on April 25 at the age of seventy-one years.

Dr. THEODORE BANGE, an ex-coroner of Hamilton County, Ohio, and member of the Cincinnati Academy of Medicine, died Monday of diabetes. Dr. Bange was born in Germany on October 2, 1856, and came to this country when he was seventeen years of age. He was a graduate of the Cincinnati College of Pharmacy and of the Miami Medical College. In 1890 he was elected Coroner of Hamilton County on the Republican ticket and served one term.

Dr. HENRY M. COX, for the past twenty years a medical inspector in the New York Health Department, has recently died, after a short attack of pneumonia. He was a graduate of Union College, Schenectady, and the College of Physicians and Surgeons, Columbia University.

Dr. CHARLES H. WINSLOW, a retired physician, of 44 Manhattan Avenue, New York, died on April 29, at the residence of his son, Herbert H. Winslow, the playwright, in New Rochelle. Two weeks ago he was stricken with paralysis. He was born in Charlemont, Mass., seventy-two years ago.

Dr. LOUIS DRESCHER, at one time a well-known physician of New York, who denounced the pomp and display of funerals, had his last request complied with on May 1, when his remains were cremated at Fresh Pond, L. I. He also asked that his ashes be cast to the winds and that no notice be made of his death in the newspapers. Dr. Drescher was eighty-three years of age and was born in Germany.

Dr. ROBERT MCLELLAN READ of Boston died at Los Angeles, Cal., April 21, at the age of fifty-six years.

Dr. CHARLES F. BRUCKNER of Cincinnati died at his home after six weeks' illness. He was born in Germany, and had lived in this city for thirty years.

Dr. EDWARD LIVINGSTON TRUDEAU, Jr., son of Dr. Edward L. Trudeau of Saranac Lake, died of pneumonia on May 3 at his residence, 722 Park avenue. The deceased was thirty-one years of age and was born at Saranac Lake. He graduated in arts from Yale University in 1896. From Yale he came to New York, graduating from the College of Physicians and Surgeons here in 1900. In December last he was married to Miss Hazel Martyn of Chicago. He was a member of the University and Yale Clubs, and had charge of clinics at Bellevue and Vanderbilt Hospitals.

Dr. E. B. HERR died at Lancaster, Pa., on April 28 at the age of seventy years. He was a member of the Pennsylvania Legislature in 1869–70.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

RELATIONS OF MENTAL DISEASE; INEBRIETY, EPILEPSY—TORSION OF FALLOPIAN TUBE—TINNITUS—INTESTINAL OBSTRUCTION FOLLOWING TYPHOID FEVER—HÆMATURIA—LISTER INSTITUTE—ITEMS—OBITUARY NOTES.

LONDON, April 15, 1904.

DR. ROBERT JONES, superintendent of the County Asylum at Claybury, has given some important facts and opinions on "the relation of inebriety to mental disease." Out of 116,000 cases of insanity in our asylums at the present time, he estimates that not less than 11,000 males and 6,000 females owe their state directly or indirectly to drink. The statistics of the London County asylums for the decade 1893-1902 inclusive, show that during this period 35,916 patients, 16,356 males and 19,560 females, were admitted into these institutions. Of these, 21 per cent. of the men and 11 per cent. of the women owed their insanity to drink alone. At the Claybury Asylum the proportion has been 22.7 of the males and 13.1 per cent. of the females. His experience had been disappointing as to actual recovery, for these patients are so apt to relapse after discharge, if they taste alcohol in any form, and only very few will pass their lives without tasting it.

The mental condition of epileptics in relation to prognosis was the subject of a paper read at the Medico-Chirurgical Society, on Tuesday, by Dr. W. Aldren Turner, who based his statements on 161 colony cases. Sex had not a great influence, but males are more frequently epileptic than females, as 91 to 78 per cent. The highest degree of dementia was more common in females. Family predisposition to epilepsy and insanity favored mental impairment. The duration of epilepsy also influences the mental state, the earlier fits appear, especially in infancy and childhood, the less is the probability of the mental state being unimpaired. The profoundest degree of dementia is mostly met with when major and minor attacks coexist. The more frequent the fits the greater mental impairment. Fits recurring in series are accompanied by a high degree of dementia. Dr. Turner holds that the interparoxysmal mental condition is one expression of a neurosis, the fits being another. Out of his 161 cases he found 13.6 per cent. intellectually normal, 31.6 had impaired memory, 25.4 were feeble-minded, and 29.1 demented.

Dr. Fletcher Beach attributed the greater mental deterioration of cases beginning in childhood to the nervous instability of early life and the want of education. He had observed great improvement in epileptic children as their education progressed. It is well known that mental impairment is often more marked in minor than in major epilepsy.

Dr. Bond said, from his observations so far at Epsom colony, lately established by the County Council, he had noticed that first-born children were more often epileptic than others, and he suggested that this might be brought about by the more difficult labor of the primipara. Another factor he thought might be the youth of parents. The fits were not the disease, the essential nature of which is as yet unknown.

At the Obstetrical Society, Dr. Hamilton Bell read a paper on "Torsion of the Fallopian Tube." As in all recorded cases the diagnosis from twisted ovarian pedicle has never been made previous to operation, and the several obstetric surgeons who commented on the paper agreed that diagnosis was mostly impossible, the subject is of little more than academic interest.

Tinnitus is so distressing a complaint in many cases that patients will ask for severe measures. There is a field for the study of pathologists in this trying malady. In a case described by Messrs. Wallace and Marriage, a young woman of twenty-two suffered so much that an attempt was made to divide the eighth nerve as in the operation for exploring the posterior surface of the petrous bone. Noises were present the next day, no facial paralysis. The wound showed no reaction and continued to discharge. Patient sank and died on the twenty-first day. At the post-mortem a fine strand of the nerve was found to have escaped division. No meningitis; internal ear normal. Dr. F. Buzzard, who examined the nerve, reported that the vestibular and two-thirds of the coeliac nerves had degenerated as a result of the resection. Mr. C. H. Fagge said he had not found it difficult to expose and excise the eighth nerve and mentioned two cases. He thought tinnitus more frequent after mastoid operations than usually supposed, that it had probably a peripheral origin. Dr. P. Weber said Alt had found leukæmic infiltration of the nerve.

Intestinal obstruction is so rare a result of typhoid fever that I do not remember any author mentioning it; but two cases were brought before the Clinical Society on the 25th ult., by Dr. E. W. Goodall. Both seem to have been caused by a local peritonitis after ulceration, which would seem to be an efficient cause, so that it would not be surprising should the lesion be more frequent. The first of the two cases presented was in a boy of fourteen, admitted toward the end of an attack of the fever. There had been some abdominal pain late in the case, and a relapse took place with pains, vomiting, etc. Three weeks later a second relapse proved fatal, and at the post-mortem the small intestine was partially obstructed about 2½ inches above the valve by a fibrous band arising out of a patch of local inflammation opposite a deep ulcer. The other case was even more noteworthy It occurred in a young man of twenty-two, who was operated on for perforation on the twentieth day of the fever, and then there was no peritonitis. A fortnight later symptoms of obstruction appeared, and he died suddenly from another perforation. At the post-mortem many small bands were found compressing and kinking the intestine, and the second perforation, about six feet above the valve, in an ulcer just above the highest band. The president said he had never seen or read of such a case.

At the same society, Mr. Walter Spencer related a case of fatal hæmaturia in a man of forty-four, admitted in an almost pulseless state, extremely anæmic and dyspnœic and a history of a fortnight's duration of the bleeding. Temperature fell to subnormal and he died within twelve hours of admission. Careful post mortem failed to find the origin of the hemorrhage and microscopic sections of the kidney, bladder wall, and aorta revealed nothing except that the wall of aorta seemed rather thinner than usual at his age. Mention was made of varicose veins in the ureter and minute ulcers in the bladder, undiscoverable when it was collapsed as lesions which might possibly have existed.

The sudden death of Sir Philip Smyly this day week cast a gloom over Dublin, and also over many professional circles here, for he was well known to many of us and greatly esteemed. He was seized, when at dinner the previous evening, with cerebral hemorrhage and did not recover consciousness. He was the son of Josiah Smyly, a distinguished Dublin surgeon and great nephew of the late Sir Philip Crompton Bart. He was an alumnus of Trinity and took his M.B. in 1860. In the same year and the next he took the licences of the two Dublin colleges, and then spent some time on the continent. On returning he obtained the surgeoncy of Meath Hospital. In 1863 he added the M.D and the Fellowship of the Surgical College to his diplomas. In 1878 he was elected president of that college, being then only forty years of age (as he was born in 1838). From 1893 to 1900 he represented his college in the General Medical Council, the meetings of which gave us the opportunity of renewed meetings with him. He was knighted in 1892. In 1895 was appointed surgeon-in-ordinary to Queen Victoria, and in 1900 the appointment was continued to King Edward. Many other distinctions came to him, and his professional position was in the front rank for many years, and his practice as a surgeon one of the most extensive. All the highest honors fell to him and no one felt jealous of his great success, so that he passes from us unenvied and leaves behind the regrets of the whole profession and thankfulness for a noble example.

Last Friday also died Deputy-Surgeon General Edmund Eyre Lloyd, I.M.S., aged seventy-five. He retired in 1885 after thirty years' honorable service. He was for some time Zillah surgeon and superintendent of the Tanjore gaol.

Intelligence comes to hand of the death, at Lucknow on March 24, of Colonel Robert de la Cour Corbett, D.S.O., Principal Medical Officer of the Oude and Rohilcund districts, aged sixty. He was educated at Queen's College, Cork and Trinity, Dublin, joined the A. M. S. in 1867, became surgeon-major in 1879, served in the Burmese expedition, 1886-87. He was mentioned in despatches, received the Burma medal and clasp and the Distinguished Service order. He was gazetted colonel in June, 1898, and the following September appointed administrative medical officer in Bengal. He was elected F.R.C. S.I in 1880.

A nonogenarian surgeon, Joseph May, F.R.C. S., of Devonport, passed over to the majority on Sunday. He qualified in 1830, and has died at the age of ninety-six. When Charles X fled in 1831, he went to Paris and helped attend the wounded in the hospitals. Later he entered the Polish army, was Surgeon-Major at Mjordowa Hospital, and was present at the siege and fall of Warsaw. On his return to England the next year, he settled at Devonport, where he has lived ever since, and was of late spoken of as the "oldest inhabitant." He took an interest in municipal affairs, had been a member of the Corporation since 1861, and was four times elected mayor.

Inspector-General W. T. J. Haran, R.N.K.H.S., died on Sunday, aged seventy-four. He entered the Naval Ser-

vice in 1850, and retired in 1888. He had a distinguished career, had taken part in the suppression of the slave trade. In the Crimean War he had much service; was at Eupatoria, the capture of Kertch, and in various night attacks on Sebastopol. He held the Turkish and Crimean medals with clasps for Azoff and Sebastopol. Later he accompanied the mission to Dahomey. He also held the Gilbert Blane medal.

The death of Dr. Arthur Garrington, Edinburgh, 1859, Surgeon to H. M. Prison at Kingston, near Portsmouth, has occurred at the age of sixty-eight. He practised throughout his life at Portsea, of which he was a native and where his father had practised for some fifty years.

Dr. E. Donaldson, surgeon to the Londonberry Eye and Ear Hospital, died on April 7, aged forty-nine.

At the meeting of the Hospital Saturday Fund, it was reported that the receipts had reached £23,674, the largest amount recorded in the history of the fund.

The Lister Institute has issued an illustrated pamphlet giving an account of its work and containing notes on serumtheraphy by the medical staff. There is a convenient account of the origin and use of the several sera and directions as to their application.

A child sent for a doctor in the night, on ringing the bell, was asked what was wanted and replying, "It's me," ran away. As the patient died, an inquest was held, and for once the coroner did not blame the doctor—nor did the jury.

Another sapient coroner, objecting to order a post mortem, said, "if the doctor is not able to give an opinion I will give one myself. It is monstrous to say a post mortem should be held in such a clear case." If that is an inquiry —what is the the use of a jury or any opinion besides a coroner's?

THE OLD-TIME GENERAL PRACTITIONER HAS NOT PASSED.

To the Editor of the Medical Record:

Sir: In these modern days of highly-refined specialism, when the human economy has been resolved into districts of suitable size and parceled out among properly differentiated experts, that somewhat modest and self-abnegating individual known as the general practitioner would appear to have lapsed into a state of more or less complete obscuration. One might gather from the current prints that he has "passed" altogether, even in the country districts. And in good truth if our willing and obliging confrères, the specialists, get all the work they appear to consider themselves entitled to, the all-round main portion might well be limited to an occasional case of diarrhœa or general debility.

These, however, your correspondent is constrained to believe, are mere surface indications. He who is willing to scratch down a little bit will find that the old-time general family doctor is still doing business at the ancient stand, quite unmoved by the multiplex proliferation of new species in his environs. To be sure, he has been aided in many sections by new and improved methods of communication and locomotion. He can secure the assistance in an emergency of a neighboring practitioner in his own or the next town, village, or crossroads with greater facility in 1904 than in 1850, or even in 1880. But his work still covers most of the departments of medical practice, and self-reliance must be his watch-word. The writer is well acquainted with a medical practitioner in a small town in Alabama, whose round of duties on a recent day comprehended, in addition to his customary medical cases, a difficult forceps delivery, the reduction of a dislocated shoulder, the sewing up of a scalp wound, the lancing of a tonsillar abscess, the tamponning of the posterior and anterior nares for a bad nose-bleed, and the extraction of a decayed and refractory molar. The doctor is his own druggist, and he is obliged to prepare and supply his own prescriptions. Possibly, his operative cases were not all handled with the same degree of nicety they would have received in a New York surgical amphitheatre, but the patients are all alive, and no doubt willing to trust the doctor in future exigencies.

But his duties among his neighbors are far more varied than is indicated by the above showing. He is consulted about all kinds of diseases occurring among the four-footed and feathered residents of his bailiwick. When times are a bit dull and his work among his human patients not too pressing, he is willing to give the farmers roundabout the benefit of his anatomical knowledge in such little matters as castrating colts and young bulls; and he has certainly performed more than one successful feline oophorectomy. As the doctor is the superintendent of the local Sunday-school, it is beyond question that he is quite capable of administering proper spiritual comfort, or in case of necessity, of conducting a satisfactory funeral service. He is the one indispensable man of his community, and can bear anything his neighbors are able to give him. This is by no means an isolated example of the twentieth-century country doctor, but a type of which our country is filled. Because they belong to a later period is no sufficient reason for differentiating them from practitioners like good old Doctor Rial Strickland mentioned in your editorial column last week. These men may not be quite so "bustling," but they are just as resolute—just as courageous, independent, and self-reliant and, withal, a good deal wiser, than their predecessors of the century just passed.

The city general practitioner does not, of course, embrace so varied a scope in his work. He resorts with far greater frequency to his friend, the specialist, and the trend is but seldom upon the domain of the dentist or the druggist. But the advance of knowledge along special lines has detracted nothing from his dignity, his carefulness, or his importance. He holds his position of trust and esteem in every home, and it is he and not the specialist who is sought when grim pestilence crosses the threshold and the hearts of the family circle are wrung by fears and forebodings. It is the family doctor who sits enthroned in the confidence and affection of the people, and sad, indeed, is the lot of the specialist who has no following in his ranks.

The general practitioner may face the future with serenity. His calling is older than the dawn of history, and while the lines of specialism will no doubt be variously recast, the family doctor with his cheering presence, his sympathetic friendship, and his unhesitating devotion will always hold that position of honor and love which constitutes the sweetest reward of his strenuous and unselfish life.

J. K C.

New York, April 26, 1904.

STATEMENT BY PROF. AUGUST FOREL.

To the Editor of the Medical Record:

Sir: From August, 1879, until March, 1898, I was the director of the Burghölzh Insane Asylum and professor of psychiatry at the University of Zurich, and desire to make the following statement: Dr. Carl Bertuhringer, who has designated me as a representative of the so-called Koenig Medicine Co. of Chicago, and who incidentally represents himself as a former assistant of Professor Forel at the Burghölzh Asylum, was *never* my assistant and never an assistant at the Burghölzh Asylum. He did, indeed, study medicine in Zurich, and, like other students, studied psychiatry with me, and practised in the clinic as a so-called "Practikant," as did other students. Under these circumstances I once permitted him to hypnotise one patient. But he was never either my asylum or my private assistant, and hence has no right to publish himself as such.

Another Dr. Bertuhringer (Dr. Hans Bertuhringer) was actually assistant physician in Burghölsh, and is now second physician at the Rheinan Asylum, Canton, Zurich. But this is quite another person.

Dr. August Forel,
Former Professor at the University of Zurich.

Chiguy, Switzerland, April 6, 1904.

Tubercle-like Bacilli in the Discharge of Chronic Purulent Otitis.—A. De Simoni says that it has recently been shown that bacilli exist which are quite similar to those found in tuberculosis, as far as morphology and coloring reaction are concerned. They can be differentiated by a peculiar growth on artificial media and by animal experimentation. These bacilli occur very frequently in milk and in commercial butter. They were also found present in infusions of several field herbs, and in the fæces of herbivora, particularly in the fæces of milk cows, who let fall the bacilli in the milk during the act of milking, united with little bits of fæces that adhered to the skin. The knowledge of these bacilli is important from a practical point of view, for it is evident that the simple morphological examination of acid-resisting bacilli is no longer a sufficient evidence nor a proof of the tuberculous nature of a lesion, and does not invalidate the necessity of further researches, which will be sure to demonstrate the widespread occurrence of this tubercle-like bacillus. Acid-resisting bacilli are found in the discharge of purulent otitis; they are non-pathogenic and resemble bacilli found in milk and in bovine fæces. They should not be confounded with the smegma bacillus, which cannot be cultivated on artificial media.—*Annals of Otology.*

Progress of Medical Science.

The Boston Medical and Surgical Journal, April 28, 1904.

The Use of the Cystoscope in Determining What Operation Is Advisable in Prostatic Hypertrophy.—F. C. Balch declares that the use of the cystoscope in connection with other methods of examination commonly used, often gives very valuable information in regard to the treatment of prostatic hypertrophy. A general anæsthetic is not usually necessary, as cocaine takes away nearly all the pain. The urethra must be large enough to admit the instrument, and the bladder must be capable of holding about five ounces of fluid without trying to expel it. Otherwise, general anæsthesia will be required. The view of the prostate may save serious mistakes. So many improvements in instruments have been made that the process has been greatly simplified. The value of the cystoscope as an aid in operation is more apparent when the galvano-cautery is to be used than when the more radical operation of enucleation of the prostate is intended. It is a great help to know just what the condition of the bladder is, and whether there is to be considered only an enlarged prostatic gland or some complication in combination with it, such as a stone or some tumor of the bladder wall.

Journal of the American Medical Association, April 30, 1904.

A Case of Parasitic Hæmoptysis.—A. D. Mackenzie reports the case of a Japanese with hæmoptysis due to the Distoma Westermanii. He calls attention to the necessity of recognizing this cause of hæmoptysis, as infection with the parasite causes emaciation, general weakness, and anæmia, such as are observed in early tuberculosis. The microscope shows the absence of the bacilli and the presence of the distoma. The author believes this to be the first recorded case of the kind in America. It occurred in Oregon, the patient having been employed in the fish canneries of Vancouver and adjacent regions, but it was concluded, from a study of the case, that the infection had been contracted in Japan.

Surgical Results in the Philippines.—From an extensive army service, J. M. Banister concludes that the prognosis of operations in the Philippines is practically as good as it is here at home. He advances the following propositions: (1) Aseptic results will just as surely follow aseptic methods in the Philippines as in the United States or in Europe. (2) Should septic infection occur in any clean case subjected to operation in the Philippines, blame the technique, not the climate. (3) Successful attainment of the object, for which operation has been undertaken, will follow careful and skilful surgery in the Philippines with the same regularity that we have been accustomed to observe in such work at home. (4) Convalescence after surgical operations in the Philippines is rapid and satisfactory, when such operations have been carefully and skilfully performed. (5) The danger of mortality after a skilfully performed surgical operation, in which all the details of a rigid aseptic technique have been carried out, is not increased by the influences of the climate of the Philippines unless the patient is, at the same time, the victim of some other serious disease.

Routine Method of Detecting and Differentiating Reducing Agents Found in the Urine.—The following are the conclusions of W. G. Doern: (1) The copper and bismuth tests are reliable negative tests, but a positive reaction must be confirmed. (2) Trommer's test is not always reliable. (3) Fehling's solution is not permanent. (4) Haines' solution is the most convenient of all copper solutions. (5) Bismuth solutions are not reduced by the alkaptons, and serve to differentiate them from other reducing agents. (6) The fermentation test is in itself not characteristic, nor is it very delicate, but it serves to differentiate lactose, glycuronic acid, hippuric acid, the alkaptons and the pentoses, which do not ferment, from levulose and dextrose. (7) If the completely fermented urine should still reduce the copper solution, it indicates the presence of glycuronic acid or alkaptons. (8) Phenylhydrasin test is good, but the technique is complicated. (9) Pentoses may be recognized by the orcin test. (10) Alkaptons are recognized by the characteristic ozonized alkali test. (11) Finally, we can differentiate dextrose from levulose by a polariscopic examination.

Cæsarean Section for Placenta Prævia.—J. B. Deaver has found recorded twenty-five cases. In sixteen in which delivery by cæsarean section was a method of choice, and not of necessity; the maternal mortality was 18.75 per cent. and the fetal mortality 56.2 per cent. as against 25 per cent. maternal and 87.5 per cent. fetal in the remaining cases in which delivery by the natural method was impossible. But in this last series—in which cæsarean section was imperative—of seven fœtuses so delivered, no less than six were already dead or not viable, only one in the series recovering, thus making the improved fetal mortality 50 per cent. In view, therefore, of these figures, Deaver declares cæsarean section is not a method to be unreservedly recommended in placenta prævia, but that it should be confined, when a choice between it and obstetric delivery is possible, to those patients whose cervix is with difficulty dilatable, whose birth canal is rather contracted, in whom immediate extraction of the fœtus is necessary, and in whom further hemorrhage would almost certainly kill either mother or child, or both. He records one personal case seen in consultation in which both mother and child were saved. The operation was called for in the judgment of the consultants, on the following grounds: Previous deliveries by forceps, all of which were difficult, in addition to forced dilatation, version and perhaps forceps again; the risk to the child's life, danger to the mother, both from hemorrhage and injury to maternal parts; and in favor of delivery by abdominal section, the much less risk to the mother and the practical certainty of saving the child, labor being but a few days of full term.

Medical News, April 30, 1904.

Treatment of Bronchopneumonia in Children.—W. P. Northrup emphasizes the following points in the treatment of bronchopneumonia in infants: (1) Castor oil clears the field of operation. It is the first aid to the injured. (2) Fresh cool air reddens the blood, stimulates the heart, improves digestion, quiets restlessness, aids to ward off toxæmia. The temperature of the room should be regulated inversely to that of the child. The patient's feet must always be warm, and the head cool. (3) Plenty of water should be used, both inside and outside; the temperature should be regulated by that of the child. (4) The child must have quiet and rest, and undisturbed sleep. (5) Correct feedings are necessary to avoid fermentation and gas in the abdomen. If there is need of them, hot salines should be used. (6) No coal-tar products should be used. Heart stimulation is not always needed. Hot salines and hot foot-baths relieve the embarrassment of the heart.

A New Method for Transillumination of the Stomach by Means of Fluorescent Media; the Value of Fluorescin, with a Research into Its Properties.—Robert Coleman Kemp describes this method as follows: The patient is given 8 ounces of water in which xv to xx grs. of sodium bicarb. are dissolved to neutralise stomach acidity. This is followed by 8 ounces of water in which are dissolved gr. xv–xx sod. bicarb., 1 drachm of glycerin, and gr. ½ of fluorescin. The patient is then taken into the dark room and the Lockwood electric light (gastrodiaphane) is introduced like the stomach tube. A certain amount of manipulation is necessary in order to determine the lower margin of the stomach at the point of maximum intensity of the light. By pressure on the abdomen and manipulation in forcing the light into the organ for the full length of the carrying tube, the lower border can be accurately located. Moreover, manipulation is at times necessary to determine the relations of the lesser curvature to the diaphragm, a point of differential diagnosis between simple dilated stomach and gastroptosis. With the new method of transillumination with fluorescent media, especially with fluorescin, it is generally unnecessary, and comparing the results with those of water as formerly employed, the writer believes the improvement to be marked as well as a scientific advance. The differentiation of tumors of the stomach, liver, and intestines is rendered easier.

The Behavior of the Costal Arch in Diseases of the Abdominal Organs and Its Importance as a Diagnostic Symptom.—Ellsworth Eliot concludes that: "The symptom of costal resistance may always be elicited in the acute and subacute inflammatory processes of the contiguous underlying organs. In chronic inflammation of these same organs it is present irregularly, either generally when the organ is increased in size, or during a transitory exacerbation of the chronic inflammatory process. In neoplasms or cysts, increased costal resistance may be obtained only when the tumor has reached a sufficient size to mechanically interfere with the movement of the arch. The degree of resistance is in direct ratio to the intensity of the inflammatory process. The increase of costal resistance is most marked in that segment of the costal arch which is situated closely to the original point of infection, or, in the case of neoplasm, to that part of the arch which lies over the most prominent part of the tumor. Its value as a diagnostic symptom is greatest in pathological conditions invading the upper half of the abdominal cavity, especially of the liver, stomach, pancreas, gall-bladder, spleen, duodenum, kidneys, and in extensive aneurysm of the abdominal aorta. In cases of empyema, only when the abscess-cavity occupies the lowest part of the thoracic cavity is there resistance of the costal arch proper. The presence of asymmetry in the elastic

recoil is very much less frequently observed than asymmetrical increase in the costal resistance, the former being present only in cases of cysts, neoplasms, and inflammatory exudates in which the acute symptoms have subsided, while it is invariably absent in all the acute and subacute inflammatory. With the subsidence of the inflammatory process, whether by radical or palliative procedure, the costal resistance again returns to its normal condition. The presence of this symptom is very valuable not only in facilitating accurate diagnosis, but also in serving as a useful guide to that incision through which the inflammatory focus may be most rapidly exposed and satisfactorily treated. The proper and skilful technique in determining the presence or absence of this symptom may be easily acquired, and therefore the application of the symptom may be utilized by the general practitioner and not confined to those engaged in the pursuit of any particular specialty.

New York Medical Journal, April 30, 1904.

Epigastric Hernia.—C. G. Cumston defines this variety of hernia as a rupture occurring at any part of the linea alba between the tip of the sternum and the navel. He reports two cases due to subperitoneal lipomata, two to a preformed defect in the fibrous tissue of the linea alba, one due to trauma and coming on acutely, and one due to pregnancy. He regards the prognosis in all such groups as good. Trusses are of little value. The proper plan of treatment is to do the radical operation, which simply consists of a cutaneous incision over the tumor, which exposes the lipoma that is practically always present, and when this is dissected out the neck of the sac should be sought for. The sac is then opened, and the contents, if any, are returned into the abdominal cavity. The sac is then ligated behind the neck and the linea alba closed by any device that may suit the surgeon, but it has always seemed to the writer that overlapping and mattress sutures have given the best results.

A Plea for the Earlier Diagnosis of Uterine Cancer.—E. H. Maier shows that the mortality from uterine cancer is undergoing a reduction. This reduction is due to earlier diagnosis and a greater willingness on the part of patients to submit to operation. He believes that we can conservatively accept in the absence of a more tangible explanation the view that trauma is often responsible for at least the propagation if not the cause of the disease. The fact that women suffering from the so-called condition of "cancerophobia" are comparatively free from the disease should be regarded not altogether in the light of a coincidence, but rather the relation between this immunity and the constant medical surveillance which the patient is under, should be considered. Finally, since the healthy uterus is less liable to undergo progressive malignant changes, a highly important element in prophylaxis should be to keep the uterine mucosa in as normal condition as possible, and under no circumstances to neglect lacerations, inflammation, and erosions, especially during the menopause.

American Medicine, April 30, 1904.

Temporary Sutures for Hæmostasis.—William C. Wood explains the method he uses to control bleeding. It consists of the application of a temporary deep suture passing under the artery, either in the wound itself or above it. The suture may be of catgut, of silkworm gut or of silver wire, or in a great emergency of strong linen thread. Thus with little more danger of sepsis than would result from giving a hypodermic injection, the physician can control the bleeding, and then have time to proceed with preparations for an aseptic operation if this is necessary. This is an emergency method and a most valuable one.

Surgery of Urinary Tuberculosis in Women.—Guy L. Hunner presents the following general summary of his paper: Tuberculosis of the urinary system is a surgical disease, being, as a rule, unilateral, and often the only focus of tuberculosis in the body. If the disease is bilateral and there are no pronounced symptoms referable to the kidneys, the treatment should be that usually accorded tuberculosis of the lungs, viz., suitable climate, nutritious diet, and proper regulation of the patient's rest and exercise; but if one or both sides begin to cause marked local or general manifestations, surgical intervention is often of great benefit. In case of bilateral disease, or in associated disease of the lung, the anæsthetic is of great importance. Local cocaine anæsthesia may be used for nephrotomy, and nitrous oxide gas for nephrotomy, nephrectomy, or nephroureterectomy. Thickened ureters are generally tuberculous, and should be removed with the kidney if the patient's condition justifies. Bladder disease in these cases is often non-tuberculous, and removal of the diseased area should not be attempted at the first operation. If the bladder fails to heal within a year under ordinary methods of cystitis treatment, the disease is probably tuberculous, and if not occupying more than half of the bladder, it should be excised.

Family Periodic Paralysis.—George E. Holtzapple reports his observations of this disease which he has seen in a family extending now along some branches, through a period of four generations. A typical case of this peculiar affection is characterized by periodic flaccid motor paralysis involving all the voluntary muscles, except those of the face, eyes, tongue, organs of speech, of deglutition, and of the sphincters of the rectum and bladder. The paralysis may be partial or complete, local or general. It may be confined to the neck, or half of the body may be completely paralyzed, while partial paralysis affects the other half. The attack may be partial in the morning and become complete during the day. There are absolutely no psychic symptoms. The mind remains perfectly clear. The onset is almost always at night, and is ushered in during sleep, with either very slight or no premonitory symptoms. The patient may retire with a feeling of weakness in the extremities, or he may have a voracious appetite which, if satisfied by rich food, is sure to precipitate an attack. Many of the patients have suffered from periodic sick-headache, which the writer regards as equivalent to an attack of paralysis, both having a common cause, whatsoever that may be. None of the special senses has been involved in these cases. It is not uncommon for one of these patients to be perfectly helpless at 7 A.M., and at 11 A.M. be engaged in doing a hard day's work without the slightest inconvenience. The writer believes that the disease is not considered serious. A number of the cases which he has observed have died in an attack. The pathology of this disease is not understood. The writer regards this condition as a vasomotor neurosis, affecting the blood-supply to the anterior horns which are almost wholly supplied by the anterior spinal artery. He has treated these cases with large doses of bromide with caffeine. This treatment has been followed by unmistakable relief, and has a very decidedly abortive influence.

The Lancet, April 23, 1904.

Reno-renal Reflex Pain.—D. Neuman reports three cases of this peculiar condition, in which the symptoms pointed to the sound kidney being the diseased one. Case 1 presented pain simulating renal colic on the left side, of five years' duration, but other signs and symptoms pointed to calculus of the right kidney. Operation showed stone in the latter. In Case 2, symptoms of calculus on the right side had lasted a year and a half. The *x*-ray detected stones on the left side. These were removed and the right-sided pain disappeared. Case 3 was one of pyonephrosis limited to the right side. Albumin and pus were found in the urine, while pain was most marked in the left lumbar region; nephrectomy resulted in cure.

Anthrax Infection of a Compound Fracture.—P. Paterson's patient was a man whose work was to mix animal's hair with lime in making mortar. He fell and received a compound fracture of the humerus. Two days later sloughing appeared about the wound, and, owing to his serious condition, disarticulation was done at the shoulder. His subsequent history was uneventful. Cultures made from the wound discharges showed anthrax bacilli and staphylococci derived probably from the materials in which he worked.

The Mental State in Myxœdema.—H. Wolseley-Lewis declares that the changes in the mental condition of those suffering from myxœdema are almost confined to the sphere of action. It seems necessary to suppose that either some toxin in the plasma surrounding the motor cells inhibits the chemical processes which originate a motor impulse or that the absence of some substance from the blood interferes with the discharge. This toxin is neutralized or this essential substance is supplied by the administration of thyroid extract; the patients get well, and keep so as long as they continue to take thyroid. He has observed that the simultaneous exhibition of syrupus ferri iodidi appears to assist its action. We see this class of patients described by such terms as dull, listless, apathetic, taking a long time to comprehend and to answer questions, of sluggish ideation, of sluggish mentation, demented, depressed, moping, lethargic, suspicious, of impaired memory, sleepy, torpid, discontented and irritable. He suggests that this proves on careful inquiry to be but part of the truth, and that the majority of these cases are sent to an asylum in error and could be as well treated outside one.

Some Forms of Pseudo-appendicitis.—According to Professor Bollentint appendicitis attacks may be simulated by entero-typhlocolitis, or, as he styles it, intestinal lithiasis. Differential points are the following: The subject who is attacked by appendicitis is nearly always seized unawares in the midst of robust health. In attacks of entero-typhlo-colitis there has nearly always been a period of digestive troubles which the patient will remem-

er even if he has never examined his stools and if he is naware that he is suffering from entero-typhlo-colitis. le will recollect, when interrogated, that he has already ad attacks of pain in the left side or in the transverse gion of the abdomen. He will say that he is subject to testinal troubles, constipation, diarrhœa, especially nder the influence of cold or departure from regular diet. n appendicitis the maximum of pain is in the cæcum ry near the appendix, but in entero-typhlo-colitis the ain is not definitely localized; it radiates over the path f the colon, principally on a level with the hepatic flexure nd splenic flexure. There is another point often very ainful between the umbilicus and the ensiform appendix. n this case it is the transverse colon which is the seat of he pain. Diagnosis, then, will embrace examination of he stools to see if they contain slimy substance or even ibe membrane or sand. When the diagnosis is once etermined and all idea of appendicitis is rejected, treatent will be given for a paroxysmal attack of entero-yphlo-colitis. But it will be well to watch carefully cBurney's region and always to bear in mind the possible nflammation of the vermiform appendix with its protean orms which are so deceitful.

British Medical Journal, April 23, 1904.

The Use of Radium in a Case of Rodent Ulcer.—J. A. B. Hammond reports the following case: The patient was a man of eighty-five years, and was suffering from rodent ulcer. When first seen by the writer, it was the size of the top of a teacup, but limited to the area supplied by the second division of the fifth nerve. It was determined to try the effect of radium bromide. A small tube of 5 milligrams was used. Treatment was begun by giving an exposure daily of fifteen minutes, holding the tube within half an inch of the ulcer, without any screen, and slowly moving it over the surface. After four or five days, although there were no visible effects, the patient said the pain was less troublesome; and the exposure was then given twice a day. The discharge which had been considerable, rapidly decreased. The granulations were more healthy, but the edges of the ulcer remained unaffected. The patient finally refused to be bothered with any treatment at all. Since then the ulcer has spread deeply, the pain increased, and the discharge returned. This proves that even in such a desperate case as this, radium has a distinctly beneficial effect.

On the Administration of Chloride of Ethyl and Somnoform, Alone or in Conjunction with Nitrous Oxide or Ether.—G. W. Bampfylde Daniell describes (with diagram) a simple inhaler made by attaching together the facepiece and angle-mount of a Clover's portable ether inhaler and introducing the agent through the tap commonly found in the angle-mount, used for gas in the nitrous oxide-ether sequence. The writer states that after using this clover method, he adopted the following modifications: Instead of the hole and wooden plug in angle-mount he prefers the tap with metal tube continuation. A tap is easier to manipulate than a plug and cannot get lost. At the commencement of the inhalation instead of projecting the fluid through the tap directly from the bottle, a definite quantity is first measured out into a small tube made of thick glass. To this measure-glass is attached a short piece of red rubber tubing, by means of which it is accurately attached to the end of the tap of the angle-mount. The writer mentions a few of the advantages of this inhaler and describes the method of administration. The inhaler is so regulated that the patient inhales a dilute vapor to which he soon grows accustomed, when it may be made stronger. Accuracy of dosage is assured. The anæsthetic can be given gradually, and that after the facepiece is adjusted; this prevents coughing, holding the breath, etc. More can at any time be added if necessary, either by projecting the fluid through the large open tap or by measuring off more in the tube. The facepiece does not have to be removed at this time. The tube, if any contents remain, can be used again in hospital practice. In the event of voluntary struggling, it is easy to empty the tube by tipping it up with one finger. If the tap is turned off before the tube is fixed on, the patient will not smell the narcotic when the mask is applied. A free airway, no lint, sponge, or wool to breathe through, and no freezing vapor near the mouth or nose is of advantage. Nitrous oxide can be given as a preliminary. Bromide of ethyl can be given and measured by this apparatus. The ether chamber may be retained. Finally, the economy in the amount of anæsthetic used is an advantage. The writer has given chloride of ethyl by this apparatus with satisfactory results.

Deutsche medizinische Wochenschrift, April 7, 1904.

Ankylosis of the Maxillary Articulation Treated by Wedge Incision of the Ramus.—Konig reports a case in which, as a result of osteomyelitis in childhood, ossification of the masseter took place, with great restriction of motion of the jaw. Several operations were done without affording permanent relief, and when the patient came under the author's observation the jaw was almost entirely immobilized. On exposing the bone it was found of ivory-like hardness, so that it could not be cut with a saw. Accordingly a series of holes was made along the lines of projected section by means of the electric drill and a wedge-shaped segment of bone with its base at the edge of the maxilla chiseled out of the ramus. After the operation forcible dilatation was first employed and after that, by practice, the patient was able to secure and preserve a very good range of motion.

Decortication of the Kidney.—Thelemann stripped the capsules from the kidneys of dogs and rabbits and made sections through the cortex at varying lengths of time after the operation in order to determine the nature of the reparative process. He found that the capsule was restored in a comparatively short space of time from the remnants of the old capsule adhering to the surface of the kidney, the septa entering the renal parenchyma and the fatty capsule. The author is uncertain as to the degree of vascularization present, but as the former conditions are reproduced in fourteen days after operation, he expresses doubt as to the permanent effect of the procedure when performed for nephritis. A temporary benefit is no doubt produced by the relief of the intrarenal tension which the operation effects.

Exohysteropexy (Kocher) after Myomectomy and for Prolapse.—Lauper and Kocher describe an operation devised by the latter in cases in which fibroids have been enucleated or in which serious prolapse exists. The principal feature of the innovation lies in the fact that the uterus or its stump is brought into position extraperitoneally and under the fascial layer. For simple prolapse the organ is drawn up into the median incision until the peritoneum can be united at the upper and lower wound angles at about the level of the internal os. The ovaries are left in the abdomen. The peritoneum on either side of the uterus is affixed to it by several sutures. The fascia is then united over the uterus. In myomectomies the uterine body or the stump is similarly treated, except that a drain is carried down to the peritoneum, and in some cases the fascia also is sutured around the organ so that it comes to lie above this layer. Eight cases have been treated in this way with results satisfactory to the authors, who claim that danger from secondary hemorrhage is avoided, that there is less risk of infection, and that the operation is easy to carry out.

Berliner klinische Wochenschrift, April 11, 1904.

The Use of Scopolamin Hydrobromate in General Practice.—Liepelt warmly recommends this drug in excitement of nervous origin, mental aberration and delirium tremens. Its sedative action in these cases is more effective and reliable than that of morphine or chloral. Scopolamin belongs to the tropeins, paralyzes smooth muscle, dilates the pupil, inhibits secretion and the inhibitory cardiac nerves. In contradistinction to the other tropeins scopolamin diminishes the excitability of the cerebral cortex and is a narcotic. The author uses it hypodermically in doses of from 0.4 to 0.8 mgm., and says that it is always well borne, produces its effect promptly, and that he has never found it necessary to exceed the maximum dose of 0.001 g. Like all agents of this sort, in some instances it fails completely, but this does not often occur.

Therapeutic Attempts with Electro-magnets.—Toby Cohn describes a series of observations made on patients suffering from nervous diseases in order to determine the value of the electro-magnetic field as a means of treating these conditions. The apparatus used is complicated and produces a change of the polarity of the magnetic field many times a second. Thirty patients were subjected to systematic treatment of various neuralgias, neuroses, etc., with improvement in eighteen of the number. This was in some cases only slight and in others of short duration, and even in the most striking instances it was only symptoms that were relieved and the underlying cause remained unaffected. The author ascribes the good effect of the treatment to suggestion alone, and says that its value is yet to be demonstrated.

Münchener medizinische Wochenschrift, April 12, 1904.

Experimental Observations on Agglutination in Tuberculosis.—Schwarzkopf describes a series of investigations made on the agglutinating power for tubercle bacilli of the blood of healthy and tubercular rabbits. His results indicate the unreliable nature of the reaction. The test fluid was a preparation of human bacilli, and the animals were innoculated with either human or bovine tubercle bacilli. Healthy rabbits never agglutinated the bacilli, but the reaction failed in about one-half of the

infected animals and was especially uncertain in those treated with the bovine form. It was only after the third week that the reaction was frequently positive, and in cases tending to recovery or near death agglutination seldom occurred. Some of the infected animals gave the reaction though no demonstrable lesions were present.

The Precipitin Reaction with Material from Mummies.—Meyer made extracts of muscular tissue obtained from three different Egyptian and Greek mummies. The age of the first of these was 5,000 years, that of the second, 2,000 years, that of the third is not given. It was not possible to obtain a perfectly clear filtrate from the second specimen, so it could not be used for the experiments. Speciments one and three gave perfectly distinct and typical precipitation reactions with the serum of rabbits injected with human hydrothorax and ascites fluid. While of no direct practical value the observation is of great theoretical interest and may also be of service in solving certain anthropological and archæological questions.

Is There a Physiological Albuminuria?—Oswald cites the figures of Leube and others which show that the urine of healthy individuals who have been subjected to over-fatigue contains small quantities of albumin in a large percentage of cases. On the other hand, albuminuria is a very rare condition in those who have not been over-exerting themselves, and Henschen found on examining ski-runners that a large number of those in whom the exercise had produced albuminuria also exhibited acute dilatation of the heart. An over-fatigued person cannot therefore be regarded as in a normal state, and if the labor be pushed too far not only albumin, but casts appear in the urine. It has been found that serum albumin diffuses much more rapidly through animal membranes than does serum-globulin, but the albumin found in these cases of so-called physiological albuminuria is a mixture of globulins often without any serum albumin at all, therefore the view of those who strive to explain the phenomenon as being due simply to a less efficient "renal-filter" is untenable. Furthermore in cases of acute parenchymatous nephritis the first albumin to appear is englobulin, whereas this is rare in the chronic forms. The author therefore concludes that albuminuria appearing after exertion is not to be regarded as physiological, and that it is a more significant phenomenon than is usually supposed, since it indicates distinct parenchymatous irritation.

French and Italian Journals.

A Case of Hydrocephalus.—Chaigneau describes this case that he observed. The mother entered the hospital in the eighth month of her pregnancy. The membranes had ruptured two days before. The patient was greatly fatigued on account of the journey she had taken, and on account of the prolonged labor. The abdomen was tense, very large, and so painful that palpation was very difficult. The fœtal parts could not be made out externally. Vaginal palpation revealed a hand, and the buttocks. Dilatation proceeded quickly. The feet were easily seized, and the body was born all but the head, which remained immovable. On introducing the examining finger, a sensation of fluctuation was clearly felt on top of the fetal head. The sutures were enormous. By means of the basiotribe the head was punctured, and a large quantity of liquid flowed out. In a very short time the head was born spontaneously. The mother's condition was good. The head of the child measured 53 cm. about the large circumference; the biparietal diameter was 16 cm.; the occipito-mental, 19 cm.—*Gazette Hebdomadaire des Sciences Médicales*, March 13, 1904.

A Choreic Family.—Antonio D'Ormea records the histories of eleven members of one family, of four different generations, all of whom were affected by hereditary chorea of the grave form, and several of whom died insane. In the first two generations only one person was choreic. In the third generation four were affected, one of whom became insane. The fourth generation had four members choreic and insane, and one with chorea alone. The fifth generation were still under thirty years of age, the age at which the others became affected with chorea. The choreic movements were typical of Huntington's chorea, rendering the patients helpless and unable to speak. Not all of them had suicidal impulses, although two had them. In the fourth generation one member did not suffer from chorea, and this child was never nursed by the choreic mother, because she died at his birth. It is considered possible that this may have had some bearing on the absence of chorea in this child. The degenerative nature of the disease, its seat in the cortex of the cerebrum, and the predisposition to nervous disease acquired from the parents, indicate that the child may be affected by the poor condition of the parent and the poor quality of the milk furnished to the babe.—*La Riforma Medica*, March 23, 1904.

The Seat of Tonic and Clonic Epileptiform Convulsions.—Nino Samaja, from his experimental work, believes that the motor cortical zone is the exclusive center of clonic convulsions in the adult dog and cat. The rest of the cerebro-spinal axis can in these animals give rise only to tonic convulsions. The bulb or isthmus of the encephalon in the rabbit is the seat of clonic convulsions. In the green frog the bulb isolated from the isthmus of the encephalon is still the seat of a clonic convulsive center. The medulla in all its extent, in all the mammalia, is the seat of an exclusively tonic center; it never provokes clonic convulsions. In the green frog, the medulla provokes, on the contrary, clonic convulsions. The clonic convulsive center rises progressively in the animal scale from the medulla to the cerebral cortex. In man, the seat of tonic convulsions is exclusively basilar; that of clonic convulsions is cortical.—*Revue Médicale de la Suisse Romande*, March 20, 1904.

Two Cases of Tuberculous Enteritis with Perforation into the Peritoneal Cavity.—Chappet reports two cases. The first patient was a man thirty years old. The family history was negative. He had an attack of pleurisy in 1901, and since that time he had had a cough. When he entered the hospital he was very much emaciated; in both lungs were signs of cavity formation. Abdominal meteorism developed, and severe vomiting. There were several stools a day, very loose in character. At autopsy when the abdomen was incised, much gas escaped. A part of the small intestine was glued to the colon. A yellowish liquid escaped from the peritoneum. About thirty cm. from the ileocæcal valve a round perforation was discovered. The stomach and the duodenum were in normal condition. In the last part of the ileum there were some characteristic ulcerations. In the center of each of these there was a perforation. Ulcerations were also found in the large intestine. The second patient was also tuberculous. At autopsy nothing abnormal was found in the duodenum or stomach, but there were numerous tuberculous ulcerations in the stomach.—*Lyon Médical*, March 6, 1904.

Early Diagnosis of Vesical Tuberculosis.—Guyon declares that the diagnosis of vesical tuberculosis at an early period is before all to be made by cystoscopy. The factors are to be considered in cystitis: The frequency of micturition; pain; suppuration. The combination of these three determine cystitis. Any one symptom by itself does not clinch the diagnosis. Tuberculous cystitis may appear, however, late in vesical tuberculosis. The writer then relates the history of a patient, a young woman of twenty-one years. She had for some time suffered from hæmaturia, more abundant near the menstrual period. There was no pain. The kidneys were healthy. Cystoscopic examination revealed vesical ulcerations. At first they seemed like simple ulcerations, but they were later seen to be tuberculous. These ulcerations often heal very quickly. The treatment consists in a general tonic medication (arsenical), which aids in the cicatrization of the local foci. In this case which the writer reports, the affection is primary tuberculosis of the bladder. There is no pain. The ulcerations have a tendency to heal rapidly, so there is need only of general treatment. Surgical interference is useless.—*Journal des Praticiens*, April 16, 1904.

Blenorrhagic Vulvovaginitis in Children.—Giovanni Raffaelli writes an exhaustive paper on blenorrhagic vulvovaginitis in babies and children under twelve years. The condition is quite frequent among the lower classes who live together promiscuously. Its frequency may also be ascribed to the delicacy of the vaginal epithelium, which renders the entrance of the poison doubly easy. Direct contagion by rape is fortunately comparatively rare. The indirect may arise from sleeping in the same bed as the elder members of the family, by baths, toilet articles, clinical thermometers, public conveniences, etc. There have been severe epidemics also in children's hospitals from the use of articles in common. Autoinfection may occur from blenorrhœal conjunctivitis. The process usually involves all of the urogenital organs, though sometimes limited to the vulva, or that and the vagina. Touton and Jadasson have demonstrated that in some pathological and physiological conditions the gonococci pass directly through pavement epithelium. The author thinks that as a rule the uterine neck is not affected. This results in part from the fact that this part in children is not functionally active, that it is in an embryonic condition, and that the uterine orifice is so small, and filled with a tough plug of mucus. The symptoms are usually local; the vulva and vagina are hot, swollen, and bathed in a greenish yellow mucopus. If the urethra is involved, pus exudes from this on pressure. If the uterus is involved, there is hypogastric pain, tenderness on rectal pressure, and fever. The course of the disease is usually from a few weeks to three months. It has a tendency to become chronic especially in weak subjects. For a positive diagnosis from

ther forms of vaginitis it is necessary to find the gonoccus in the discharge. The most serious complications those involving the uterus and the tubes, and even ath has been known to occur from peritonitis. Articular eumatism, endocarditis, and pleurisy may occur. The gnosis is usually favorable. Treatment consists of ections and washes of permanganate or protargol two three times a day.—*Rivista Clinica di Pediatrica*, March, 4.

e American Journal of the Medical Sciences, April, 1904.

A Case of Prenatal Appendicitis.—W. Fred. Jackson orts the case of a girl baby who died with symptoms metallic poisoning when about forty hours old. The position is that the child died of poisoning from the inistration of bichloride of mercury with citric acid, some unknown manner. Post-mortem examination ealed an appendix much elongated and congested, g upon the cæcum, and bound down upon it by erous and firm adhesions. The surfaces of the apdix, where it was reduplicated upon itself, were firmly nd together. The small intestine and the colon w the ileocæcal opening presented no evidence of mmatory action. The mother's labor was normal. child was strong and apparently well up to a very rt time of its death. The writer thinks that the inmatory condition must have occurred previous to the d's birth. The inflammation was evidently in the e of resolution.

rcinoma of Abdominal Cavity; Remarks on Cytodiag-.—Norman B. Gwyn, after describing a case of this re, says that we are at present much nearer an accu- working knowledge on the subject of diagnosis of ignant disease by means of the character of the cells d in the exudate than ever before. In a majority of nces one may suspect malignant disease if large num- of unclear figures, typical or atypical, are present; their absence by no means excludes the possibility of gnancy. Occasional unclear figures are to be found other conditions. Endothelial cells with many nuclei probably but not certainly more numerous in cancer- exudates. Cells of exudate tending to appear in ches or groups with intercellular fibrillæ are to a e, suspicious. Small groups of lymphocytes or pus are often seen. Unusual cells of glandular or other must be given a significance of their own. Mechaniexudates show more often numbers of large endothelial , often in large plaques, the "placards" which Widal Ravant consider pathognomonic of mechanical exus or transudates.

e Clinical Behavior of the Lymph Glands in Typhoid r.—David L. Edsall declares that typhoid fever s its part so largely in lymphatic tissues that it is to pected that it should at times produce widespread dular enlargement, readily recognizable at postem, particularly since the disease is well known to be neral bacterial infection and not a local process. ically, however, in cases in which it is necessary to inguish between typhoid fever and other diseases ich glandular enlargement is common, the discovery many readily palpable glands is usually accepted as g a point in favor of the latter diseases and against hoid fever. The writer has made numerous observas on this point, the results of which he mentions in paper. He believes that in a considerable number ases, widespread glandular enlargement—slight, but palpable—occurs in this disease. It is as marked in instances as that which usually occurs in certain r infectious diseases, which is usually looked upon as ewhat distinctive of those diseases. The regions that has especially observed are the groin, the axilla, and anterior and posterior parts of the neck. In some the epitrochlear and the brachial glands were en- d. The enlargement of the glands in typhoid fever s to occur late, and often so late as to be of no diagic importance; it is also often so slight that it can rely be of much help. The writer does not believe slight enlargement of the lymph glands which he has rved can be of great importance in distinguishing condition from other infectious diseases. The chief rest in his observations he believes to be in their tion to diagnosis. Glandular enlargement, unless marked, cannot be considered a strong point against hoid fever, for enlargement of the degree usually in syphilis is not very uncommon in typhoid fever, a somewhat lesser degree is very common.

marks on Gastrosuccorrhœa and Tetanic Attacks urring with Chronic Ulcer of the Stomach.—J. Kaufn states that there are two varieties of gastrosucrhœa—the periodic and the chronic. In the periodic re are attacks of vomiting of gastric juice coming on spasmodically and lasting from a few hours to several days. The condition has been attributed to a morbid overactivity of the secretory nerves of the stomach, which is regarded as a neurosis by itself, as a symptom accompanying hysteria or neurasthenia, or as a symptom occurring in the form of gastric crises in tabes and other spinal diseases. The remaining symptoms occurring with such attacks, pyrosis, headache, gastric pains, and vomiting, are classed as secondary manifestations. In chronic gastrosuccorrhœa the conditions are entirely different. It is not of a nervous character but is dependent upon anatomical changes of the stomach or duodenum. Some authors apply the term gastrosuccorrhœa to all cases in which gastric juice is found in the fasting stomach. Others maintain that there should be a distinction between the cases in which the presence of gastric juice in the fasting stomach is only a symptom, and another well-defined group of cases for which they would reserve the term gastrosuccorrhœa. Besides gastric juice in the fasting stomach, there must be the symptoms—pyrosis, vomiting, etc.—to justify the diagnosis. As to whether this condition is a disease *per se*, a consensus of opinion has not been reached. Whenever an operation or an autopsy has afforded an opportunity to gain an anatomical basis, it has revealed ulcer or its sequelæ. As long as there is no proof that gastrosuccorrhœa may occur as an independent disease, it will be well to regard it merely as a symptom. The condition is treated by freeing the stomach from its stagnating contents. The methods usually resorted to in gastric ulcer are also used. Tetanic attacks are of serious import and often lead quickly to a fatal issue. In the latest summary of these cases by Albu, forty in all, there were thirty-one deaths—77½ per cent. mortality. It may be possible to end the attack by means of salt infusions. A recurrence can be prevented only by removing the cause. Whenever it is impossible to correct the motor insufficiency by internal means, it should be overcome by operation, either by pyloroplasty, gastroenterostomy, or resection, as the case may require. This is the rational treatment for gastrosuccorrhœa, as well as for tetany.

Empyema of Frontal Sinus, Followed by Extradural Abscess of Frontal Lobe; Operation and Death from Hypostatic Congestion of the Lungs.—Paul S. Mertens reports this case which came under his care. The patient was a man aged forty years. He was suffering from an abscess in the region of the glabella. This abscess was incised and about one ounce of pus evacuated. There was then complete and immediate relief of pain. But in a few days the pain returned. On probing the wound, necrosed bone was found, and in several places the probe seemed to enter the cranial cavity. A diagnosis of extradural abscess was made, and operation was performed. A three-inch incision was made in the integument of the forehead through the seat of the abscess. A half-inch trephine was applied to the center of the necrosed area and a button removed. An extradural abscess was found. Removing the necrosed bone opened the left frontal sinus and about one-half ounce of pus was found in it. The wound was irrigated and an iodoform gauze dressing applied. Several days later the right frontal lobe was aspirated. Pus and broken down brain tissue were evacuated. The patient's condition slowly improved for about a week, when a marked change for the worse occurred. The lungs became involved and he finally died twenty-one days after the operation, from exhaustion. The writer believes, from the condition of the brain at autopsy, that this patient would have recovered from the abscess. The pulmonary complications were without doubt the cause of death. The abscess was the direct result of the empyema of the frontal sinus.

Renal Disease of Pregnancy and Retinitis Albuminurica.—Leo Jacobi gives the history of this case. The patient, a woman of thirty-three years, was delivered twice of a macerated fœtus. The husband had had syphilis. After an interval of about two years, the patient conceived again. At about the sixth month she began to suffer with severe headaches. Other symptoms supervened—nosebleed, vomiting, diplopia, blurred vision, and impaired hearing. A right-sided facial paralysis developed. She passed but little urine. Ophthalmoscopic examination showed the presence of "retinitis albuminurica." Although the patient was kept in bed on a milk diet and treated with hot baths and antiluetic as well as eliminative medication, no improvement followed, so labor was induced. The child lived for two weeks and showed no signs of syphilis. A striking improvement followed delivery. The writer believes it most likely that a small central hemorrhage was responsible for the paralysis. He also thinks that the renal disturbance originated in the last pregnancy. He concludes that future conception in this patient will have to be prevented a tout prix.

Book Reviews.

TREATISES ON DISEASES OF THE SKIN. For the Use of Advanced Students and Practitioners. By HENRY W. STELWAGON, M.D., Ph.D., Clinical Professor of Dermatology in the Jefferson Medical College and Woman's Medical College, Philadelphia; Dermatologist to the Howard and Philadelphia Hospitals; Member of the American Dermatological Association; Associate Member of the French Society of Dermatology and Syphilography, and of the Italian Society of Dermatology and Syphilography. Third Edition. With 220 Illustrations in the Text, and 26 Full-page Lithographic and Half-tone Plates. Philadelphia, New York, London: W. B. Saunders and Company, 1904.

THOSE who are familiar with Stelwagon's Dermatology will not be surprised to learn that a third edition has come out within a little over a year after the appearance of the second. This is hardly more than a reprint, however, for dermatology is not making such rapid strides as some other of the branches of medicine. Mention has been made of the newer applications of radiotherapy, the Finsen light, Röntgen rays, and d'Arsonval currents. The illustrations, particularly the plates, are very good, some of them excellent. The colored plates are hardly as faithful as those taken from original photographs, but all will be helpful to the student and non-specialist.

DIRECTIONS FOR LABORATORY WORK IN PHYSIOLOGICAL CHEMISTRY. By HOLMES C. JACKSON, Ph.D., Assistant Professor of Physiological Chemistry in the University and Bellevue Hospital Medical College. Second Edition. Rewritten and Enlarged. New York: John Wiley & Sons; London: Chapman & Hall, Limited, 1903.

THE second edition of this manual appears as the result of a thorough revision of the original, which was issued in 1902; numerous additions to the subject matter have also been inserted. It is supposed that the use of the book will be supplemented by lectures, hence the text has been contracted within the smallest possible space. The tests for the various carbohydrates, fats, and proteids are first considered, following which muscular tissue, nervous tissue, and bone are taken up. Several chapters on the chemistry of digestion follow. The book terminates with sections on the physiological chemistry of the blood and urine, of which the latter is by far the most complete. The work is not designed to be a treatise on physiological chemistry, but essentially a collection of experiments for the use of the laboratory beginner. The author has successfully accomplished this purpose, and the work will certainly find a place in its appropriate field

DISEASES OF THE GALL-BLADDER AND BILE DUCTS, Including Gallstones. By A. W. MAYO ROBSON, F.R.C.S. Assisted by J. F. DOBSON, M.S. (London), F.R.C.S. Third Edition, 485 pages, illustrated. Wm. Wood & Co., 1904.

THE very recent progress in the domain of surgical affections of the gall-bladder and bile ducts has warranted a new, revised, and extended third edition of Robson's classical work upon this subject.

The chapter dealing with the operative technique in gallstone disease is especially good; many of the author's suggestions are excellent, and their adoption will much simplify the operations upon the biliary system of ducts. He works with a small incision through the fibers of the right rectus muscle (2 to 3 inches), prolonged, if necessary, upward and inward to the ensiform cartilage. By lifting the liver in bulk and rotating it at the same time that traction is made upon the gall-bladder, the ducts and gall-bladder are brought into one straight line, and raised up toward the abdominal wall. Access to the hepatic and common ducts and the deep parts of the cystic duct is thus rendered much freer.

Cholecystostomy is considered by Robson the operation *par excellence* in gallstone disease. Cholecystectomy is only performed in which there is extensive or malignant disease of the gall-bladder and when the cystic duct is stenosed or occluded. For exploration of the common duct Robson like all others prefers to use his index-finger, resorting only to the probe or scoop when the duct is not sufficiently dilated to permit of the introduction of the finger.

Differing from most other authorities, Robson still adheres to suture of the choledochus, after it has been incised for the removal of calculi. Suture of the duct does away with the great benefits derived from drainage, which is to-day considered of paramount importance in biliary lithiasis; and accomplishes no especial good, for if the choledochus is patent, there need be no fear of establishing a biliary fistula by drainage.

The entire text has been revised and enlarged; in the appendix at the end of the volume will be found a short account of all the operations on the gall-bladder and bile ducts (539 in number) performed by the author.

The book is well made, the illustrations are numerous, and the type is large and clear.

THE VALUE OF URETERIC MEATOSCOPY IN OBSCURE DISEASES OF THE KIDNEY. By E. HURRY FENWICK, F.R.C.S. 219 pages, illustrated. Philadelphia: P. Blakiston's Son & Co., 1903.

THIS book will be read and studied with great interest by all who use the cystoscope. The author has exceptionally well described and pictured the appearance of the ureteric orifice in diseased conditions of the kidneys, and his large experience in this field gives great value to his conclusions.

The surgeon of to-day does not rely on physical examination of the kidney, and chemical examination of the urine to establish an accurate diagnosis of kidney disease. He is frequently called upon to make a diagnosis of the health or disease of the kidney long before there are physical evidences of its enlargement or chemical changes in the urine; and to accomplish this the appearance of the ureteral orifice promises to afford considerable aid. The book opens with a chapter on the technique of ureteric meatoscopy; this is followed by brief descriptions of the appearance of the ureteric orifice in healthy and diseased conditions of the kidney—amongst the latter are considered painless renal hæmaturia, calculous disease, and tuberculosis.

The attempt on the author's part to associate a definite appearance of the ureteric orifice with each class of diseases of the kidney, is now for the first time made; although the presence of irregular ulcers around the ureteric orifice has long been recognized as pathognomonic of renal tuberculosis.

Further substantiation of the author's findings must be at hand before his conclusions can be accepted, and it is to be hoped that the seed which is sown by this work will fall upon fertile ground, and that in the near future further data bearing upon this all-important subject will be at hand.

AN ATLAS OF HUMAN ANATOMY for Students and Physicians. By CARL TOLDT, M.D., Professor of Anatomy in the University of Vienna, assisted by Prof. ALOIS DELLA ROSA, M.D. Translated from the third German edition and adopted to English and American International Terminology by M. EDEN PAUL, M.D., Brux, M.R.C.S., L.R.C.P. Second Section, Arthrology; Third Section, Myology. New York: Rebman Company, 1904.

WE noticed in these columns some months ago the appearance of the first volume of this best of anatomical atlases in existence at the present time, and now are glad to welcome the second and third sections, with the publication of which the work is half completed. The second section treats first of the articulations in general, illustrating the various kinds of joints, and then the individual joints are pictured in order, beginning with the trunk and passing on to the head and the upper and lower limbs. The same order is followed in illustrating the muscles in Section III. First we find general considerations of myology—the structure of muscle, the principal muscle forms, the relations of muscles to joints, and the fasciæ; then the individual muscles and muscle groups of the trunk, head and neck, and upper and lower limbs.

There is little to add to what was said in speaking of the first section of this excellent work. Toldt's Atlas was favorably received by anatomical specialists the world over immediately upon the appearance of the first edition, for the fidelity to nature and the artistic excellence of the plates were recognized at once as never having been surpassed in a work of this kind. The illustrations are all carefully drawn to scale from actual dissections. The work is a pure atlas with no descriptive text, but for this reason will probably prove more useful as a book of reference for the physician as well as the surgeon, than would the ordinary anatomical treatise. At all events it will admirably supplement the latter.

COOKERY FOR INVALIDS AND THE CONVALESCENT. Third Edition. Revised and enlarged. Compiled by HERMAN SENN, G.C.A., author of "The New Century Cookery Book," "The Practical Cookery Manual," "Recherché Side Dishes," "The Culinary Encyclopædia," "Ices, and How to Make Them," "Practical Gastronomy," "French Menus," etc. London, S. W.: The Food and Cookery Publishing Agency.

THAT this book is now coming out in its third edition is evidence of the popularity with which it has been received. Among the chapters are those containing special diet lists for patients afflicted with diabetes and gout. Diet for corpulency and diet in old age are treated in other chapters. The volume is a very handy one for those having the care of the sick.

THE COMMONER DISEASES OF THE EYE. How to Detect and How to Treat Them. For Students of Medicine. With 250 illustrations, many of them original, of which seven are colored plates. By CASEY A. WOOD, C.M., M.D., D.C.L. Professor of Clinical Ophthalmology in the University of Illinois; Professor of Ophthalmology in the Post-Graduate School, Chicago; Ophthalmic Surgeon to St. Luke's Hospital, Chicago; and THOMAS A. WOODRUFF, M.D., C.M., L.R.C.P., London; Professor of Ophthalmology in the Post-Graduate Medical School, Chicago; Ophthalmic Surgeon to St. Luke's Hospital and Dispensary and to St. Anthony de Padua Hospital, Chicago. Chicago: G. P. Englehard & Company, 1904.

THIS work of 491 pages is intended to succeed a short treatise entitled "Lessons in the Diagnosis and Treatment of Eye Diseases," published many years ago by but one of the present authors. This, the later volume, is greatly enlarged upon, and the subject of ophthalmology is considered solely from the standpoint of the physician in general practice.

The authors have certainly carried out their plan successfully, for seldom has there appeared a work on the eye more simply and yet more comprehensively written. It is well printed on good paper, and is made attractive by its compactness and by its neat cover. It is not always an easy matter to simplify a difficult subject like optics and ophthalmology and still make it practical and interesting and profitable reading to those little conversant with the science; yet, it must needs be, certainly, a very stupid or negligent general practitioner who cannot fully comprehend by a little persistent effort the commoner diseases of the eye met with in connection with his general practice and so well depicted in this work.

The illustrations, though often not new, are plentiful and to the point, and the table of contents and index are complete and well-arranged for quick reference.

The newer remedies are fully referred to, and the chapter on the pathogenic bacteria invading the eye is thorough and up to date.

A PRACTICAL TREATISE ON NERVOUS DISEASES FOR THE MEDICAL STUDENT AND GENERAL PRACTITIONER. By F. SAVARY PEARCE, M.D. New York: D. Appleton & Co., 400 pages, 91 illustrations, many in colors.

THE object of this book, the author tells us in his preface, is to furnish the general practitioner and student with a textbook in which doubtful points in neurology are curtailed and practical facts are presented in small compass. In the judgment of the reviewer, the object has not been attained. It is particularly in the chapters that offer opportunity for some originality of presentation, those in which diseases of the nervous system are delineated, that the shortcomings are most striking, for the introduction devoted to anatomy, physiology, and chemistry is admittedly compilation, and that not well done. For instance, on page 17, is a paragraph entitled "Pons Varolii," etc.: "This is situated between the medulla and the crura cerebri. It is a white body in the form of a half ring. Its size depends upon the size of the hemisphere with which it has to do. It weighs about 250 grains. It has six faces. The anterior face rests upon the basilar process of the occipital bone, and presents a median groove for the basilar artery. The posterior surface forms a part of the floor of the fourth ventricle." Not another word of its topography or connections: To what the "et cetera" in the title refers is not apparent. "The hemisphere with which it has to do" refers probably to the cerebral hemisphere projections from which form constituents of the pons, but why the size of the pons *depends* upon it, is not apparent. To be told that the pons has six faces, even though it had, cannot possibly convey anything worth while to him who is seeking to learn something of the pons, its connections or functions. "Irritation of the pons will cause convulsions; therefore it *contains a convulsive center*." Breathing upon the skin of individuals in certain pathological conditions will cause convulsions, but it does not follow that the skin contains a convulsive center. No more does it follow that the pons contains one for the reasons stated. In his chapter on "Symptoms and Methods of Examination" the author says the sense of the application of weight is determined by the piesmeter. This by way of simplifying matters for the student who cannot find bricks or stones to test the sense of weight. Neither "Foster's Medical Dictionary" nor the catalogues of popular instrument-makers mention piesmeters. In the chapter on "Treatment and Prevention of Nervous Diseases" the author says "Consanguinity should be avoided, nor should intermarriage take place between families of highly nervous temperaments." We do not favor one family's marrying another in any event, even though they have lymphatic temperaments. The prevalent method of two individuals marrying seems best adapted to our present needs, and inasmuch as Congress now investigates the legality of one individual marrying more than one individual, so it is likely that if one family attempted to marry another, considerable agitation would result.

"The overuse of tea, coffee, tobacco, and alcohol must be remembered as causes of various functional or organic nervous diseases, such as optic atrophy or chronic neuritis." Which of these is the functional and which the organic nervous disease, the author does not tell us. "Alcoholic abuse stands next to syphilis as a cause of a legion of diseases of the nervous system." As there are only about two score nervous diseases all told, and as in only one of them, multiple neuritis, has it been shown positively that alcohol is the cause, it may truthfully be said that the author permits himself some latitude. He may have had arterial sclerosis and its sequelæ in mind, then there would have been two—on the way to legion—but then that is not a nervous disease.

We cannot pass without protest the statement "in cases of atrophic dry skin, I have so often seen in women at the climacteric suffering from general nervousness, Turkish bathing does a great good," because it isn't clear who has the nervousness. Perhaps the writer is speaking "metamorphorically," as he accuses "Kraft-Ebing" of having done (page 362).

The following may be taken to represent the writer's understanding of nervous diseases. "By Myasthenia gravis is meant the peculiar condition in which the patient loses power periodically and suddenly, in the muscles without any definite neurological symptoms. It is closely allied if not identical with periodic paralysis." Now we maintain there is not a word of truth in that statement. But enough. We do not often permit ourselves to say all that an unworthy book deserves, and this shall be no exception to the rule. Every page reveals amateurishness and incompetency. Not one feature has the reviewer been able to find that commends it to favorable notice.

BURDETT'S HOSPITALS AND CHARITIES. Being the Year Book of Philanthropy and the Hospital Annual, 1904. By SIR HENRY BURDETT, K.C.B. Author of "Hospitals and Asylums of the World;" "Hospitals and the State;" "Pay Hospitals of the World;" "Burdett's Official Nursing Directory," etc. 12mo, 1131 pages. London: The Scientific Press, Ltd.

THE present volume shows careful editing and is up to date. In the preliminary chapters will be found some new information and an exhaustive review of the chief questions which are engaging the attention of the managers of every group of institutions, which collectively constitute the field of charity. The book contains a review of the position and requirements, and chapters on the management, revenue, and cost of the charities. A record of Hospital work for the year. A guide to British, American, and Colonial Hospitals and Asylums, Medical Schools and Colleges, Nursing and Convalescent Institutions, Consumption Sanatoria, Religious and Benevolent Institutions and Dispensaries. The section on American Hospitals comprises about 50 pages, and that on American Hospitals for the Insane, 12 pages. Information is given on the following points concerning each institution: Date of Incorporation; Name of President; Governing Body; Superintendent; Secretary; Medical Staff; Resident Medical Staff; Nursing Staff; Beds; Income; Expenditure; Special Features.

DISEASES OF THE INTESTINES. A Textbook for Practitioners and Students of Medicine. By MAX EINHORN, M.D., Professor of Medicine at the New York Post-Graduate Medical School and Hospital, and Visiting Physician at the German Hospital, New York. Second revised edition. New York: William Wood & Company, 1904.

THIS work has undergone the necessary revision, but due to the recent appearance of the first edition, little has been added.

The book is divided into chapters, the first of which gives the anatomy and physiology of the digestive tract with the exception of those already described in the author's work on "Diseases of the Stomach." The methods of examination and general treatment compose the second and a most valuable chapter. Acute and chronic intestinal catarrh, dysentery, ulcers of the intestines, neoplasms, hemorrhoids, appendicitis, intestinal obstruction, nervous affections, and intestinal parasites, are the subjects of the remaining chapters.

Throughout the work the author has endeavored to make his volume a practical one, giving the needed instruction on diagnostic points, and going into detail regarding the treatment. He has so balanced his work as to give the main bulk of it to the ordinary diseases, at the same time not ignoring the less important conditions.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held April 7, 1904.

DR. ANDREW H. SMITH, M.D., IN THE CHAIR.

THIS meeting was held under the auspices of the Section on Pediatrics.

Modes of Infection in Tuberculosis.—Dr. PHILIP S. SABINE read this paper. He considered the modes of infection in the male and in the female, reviewing a great deal of literature upon this subject. He said that many cases had been reported in which tuberculosis was present in children prior to birth, but there was an absence of clinical evidence to prove the infection to be from the male, while maternal infection was an established fact. Baumgarten claimed that the majority of cases of tuberculosis was due to heredity. There was no doubt in the minds of investigators that congenital tuberculosis was very common. Dr. Sabine then considered post-genital types, giving a statistical review of evidences of this disease as it occurred in the uro-genital tract, through coitus, through inoculation, through the air passages, the nasopharynx, the tonsils, etc. He believed that the tonsils were the chief portal of entry.

Infantile Tuberculosis; Its Portal of Entry, Topography, and Clinical Manifestations.—Dr. ROWLAND G. FREEMAN read this paper and said that tuberculosis in young children was fairly common; in 1,448 successive autopsies at the Foundling and Nursery and Child's Hospitals 158, or nearly 11 per cent., showed tuberculous disease, and this was a much lower rate than given by other writers.

Portal of Entry.—The point of infection in most cases was a subject on which the widest difference of opinion existed among the highest authorities, but the assumption that the tubercle bacilli most often gained access to the human body by the respiratory tracts seemed well founded. It was still a question to what extent the tonsil was ordinarily a point of entry of the tubercle bacilli, but the lymph nodes of the neck might be safely considered as frequently the first lesion noted after the third year, and tuberculosis of these lymph nodes often existed when there were no evidences of other tuberculous lesions. Tuberculous bronchial lymph nodes certainly formed the most common lesion found at autopsy, but they were usually associated with tuberculous lesions elsewhere. Regarding the frequency of tuberculosis due to the ingestion of food containing the tubercle bacilli, so far as he knew nobody in New York believed that he had ever seen many cases at autopsy evidently due to intestinal infection, though observers in Europe reported an entirely different experience. He thought this difference might be due to a more careful search for tuberculous lesions or to a different judgment as to what was sufficient evidence of intestinal origin. It was evident that tubercle bacilli which gained access to the body by the intestines were readily carried by the lymph stream to the thoracic duct, into the superior vena cava, the right side of the heart and out into the lungs. Living tubercle bacilli had been found to exist fairly frequently in ordinary milk, and it had been shown by Ravenel and others that bovine tubercle bacilli were pathogenic for man. It had been demonstrated that the tubercle bacilli survived the action of the gastric juice, and the fact that we found lesions of undoubted intestinal origin confirmed the fact that they could pass through the human stomach uninjured.

Topography.—The statistics regarding the distribution of tuberculous lesions in children showed that the abdominal organs were fairly frequently involved. After quoting various statistics of Froebelius, Schwer, Carr, and Biedert, he thought that we must conclude that it was impossible to state the original point of invasion. He himself had tabulated the results of 158 autopsies on tuberculous children, and these showed that there were between 1 and 3 months, 4 cases; 3 and 6 months, 21 cases; 6 and 9 months, 21 cases; 9 and 12 months, 15 cases, or a total of 61 under one year. Between 12 and 18 months, 18 cases, and between 18 and 24 months, 16 cases, or a total of 34 between the first and second year. The average age at death was later among tuberculous children than among other children, and in infancy the disease was sufficiently acute to cause death very often before marked emaciation took place. The nutrition of the tuberculous cases was not materially worse than that of the non-tuberculous cases. The distribution of lesions in his 158 cases of tuberculosis in young children showed involvement of the bronchial lymph nodes in 126, lungs in 112, spleen in 90, liver in 66, mesenteric lymph nodes in 44, meninges in 30, small intestines in 30, mediastinal lymph nodes in 28, kidneys in 20, cervical lymph nodes in 14, and large intestine in 7. As to the general distribution of the series of 158 cases, 36 had thoracic lesions only, 92 had abdominal lesions and 25 cranial lesions. In another table that showed the distribution of the lesions in 52 cases involving the mesenteric lymph nodes or intestines or both, 6 cases showed thoracic lesions but no other abdominal lesions, while 29 cases showed involvement of other abdominal organs and the thorax and 12 cranial lesions in addition.

Clinical Manifestations.—The tuberculosis of infancy was usually an acute, widely disseminated affection which, in a considerable number of cases, involved the bronchial lymph nodes and lungs. It was usually a most obscure disease for diagnosis and often a definite diagnosis could not be made until the meninges became involved. The lungs usually showed merely râles or slight changes from normal respiration, and it was only in advanced stages that consolidation appeared. The involvement of the meninges gave typical symptoms. The duration of the disease was two to three or four weeks. An unresolved pneumonia, which often it was unnecessary to differentiate from this disease, could usually be distinguished by the marked physical signs, the higher temperature, the slow course, and the much more marked emaciation.

Summary.—Tuberculosis in infancy arose most often from either the respiratory or the alimentary tract, but the comparative frequency of these two modes of infection had not yet been definitely determined. The tuberculosis of early life was most common during the first year when children were on an exclusive milk diet; and much milk contained tubercle bacilli, and bovine tubercle bacilli were pathogenic for man. At this period, owing to the structure of the intestinal wall, bacteria could probably pass through, although it was uninjured. Experiments on animals showed that inhalation tuberculosis caused usually lesions of the bronchial lymph nodes and lungs alone, and wherever the portal of entry might be, these structures became very early involved. Inoculation experiments proved that the mesenteric lymph nodes might be tuberculous without the presence of any gross lesions in them. Mesenteric or intestinal lesions could be detected on gross examination in 26 per cent. of the autopsies which he had done at the Foundling and Nursery and Child's Hospitals. The tuberculosis of infancy, unlike that of later life, was usually an acute, widely disseminated, general disease with moderate temperature and few symptoms and physical signs unless the invasion of the meninges gave rise to symptoms. Tuberculosis of the cervical lymph nodes and of the joints was rarely seen under the third year. The power to overcome a tuberculous infection that had invaded the organs apparently did not exist in infancy. While the tabulated autopsies showed a very wide distribution of the tuberculous disease in these infants, they probably indicated a much less general distribution than really existed; for the data were based on hurried gross examination without microscopical confirmation. A series of autopsies in the same institutions in which the intestines were carefully examined without separation from the mesentery, and with microscopical examination of all suspicious thickenings, he said would probably show a much greater proportion of intestinal

involvements, and a still larger proportion could be found by animal inoculations.

The Influence of Bovine Tuberculosis on Human Health.—Dr. MAZYK P. RAVENEL read this paper, and referred to the correctness of his belief in the intercommunicability of the disease, such as he had advanced for years, and he said that he had established certain facts and conclusions which were irrefutable. The study of the cultures of the tubercle bacilli in man and in animals showed no difference that could aid us in determining the origin of the disease. The tubercle bacilli had greater pathogenic power for all animals except swine. He considered the increased susceptibility in animals, the virulence of the bovine tuberculosis, the effects of bovine tuberculosis on man, etc. He reported cases in which there was great resistance to ordinary methods of treatment and cure only obtained after radical excision of the affected parts. He said that the belief that the dried sputum spread tuberculosis was the commonly accepted one, but this was not supported by clinical evidences. He said it was the bovine tuberculous material taken as food that played a part in causing human tuberculosis. Experiments had shown that the tubercle bacilli could penetrate the healthy mucous membrane and not leave any track, and the lungs might become affected through infection by way of the intestines. The figures regarding primary lesions were not at all to be relied upon because they were not at all uniform. He thought that no doubt the tonsils was the portal of entry for the tubercle bacilli in many cases, although he greatly believed in infection from the ingestion of tuberculous meat from cows. Bovine tuberculosis was a scourge, especially on farms near large cities.

The Prevention of Tuberculosis in Children.—Dr. HERMAN M. BIGGS read this paper. He thought there could be no question that the factor of so-called heredity in the causation of tuberculosis was largely explained through house infection, and this view most authorities accepted. In a family in which a case of pulmonary tuberculosis existed, an infant was seriously exposed to the danger of infection through breathing the air which might contain the bacilli, through kissing, or through the transfer of food from the mouth of the mother to that of the infant, as was frequently done, especially among the lower classes As the child grew older, it was exposed even to a greater extent because, while crawling on the floor, the hands were likely to be soiled by the expectoration carelessly discharged on the floor, or the dust that was wiped up from the floors and near-by objects, and which was transferred directly to the infant's mouth. There was also the possible infection through the use of infected eating utensils and the taking of milk from tuberculous cows. He said the infant of an infected family was more exposed to the possibility of infection than any other member of the family. There was comparatively little danger that young children would be sufficiently exposed to tuberculous disease to acquire infection until after the child had at least reached the age of four or five years—that was, outside the family. If, then, the preventive measures which had been adopted in recent years for the restriction of tuberculosis had had any considerable value, this should first be indicated in a reduction in the death rate from tuberculosis in children under fifteen years. He said the preventive measures which had been adopted in New York City during the past ten or twelve years and which consisted chiefly in the provision of hospital accommodations for advanced cases of consumption, in the disinfection of apartments, and in the education of consumptives and their families as to the nature of the disease and the proper disposal of the expectoration, should result in a lesser degree of house infection and should be followed by lower death rates from tuberculous disease in the early periods of life. Certain data showed that during the ten-year period ending in 1902 there had been a decrease of more than 40 per cent., and that during a period of twenty years the decrease had considerably exceeded 50 per cent., in the death rate from pulmonary tuberculosis and tuberculous meningitis in children under fifteen years of age.

With the extension of the regulations which were now being enforced, and a wider dissemination of information for the care of advanced cases, he looked for a still further rapid reduction in the death rate in this early period of life. It seemed to him that these data afforded perhaps greater encouragement in the crusade for the prevention of tuberculous disease than any other which were at command.

Dr. THOMAS DARLINGTON, Commissioner of Health, said there was no question in his mind that the entrance of the tubercle bacilli was by way of the lungs, and illustrated his belief by references to post-mortems that he had made upon those who had died during the construction of the Croton Aqueduct. He found, in the smaller bronchioles and practically all through the lungs, a great many particles of ground rock and dust. He believed that if the dust could so penetrate almost every part of the lungs, certainly the tubercle bacilli could gain ready access in the same way. To show how readily cattle could acquire tuberculosis, he related an instance that occurred in an institution near to New York. Consumptives were allowed to play quoits in a pasture near the hospital, and they then did not use their spit-cups but spat upon the grass. Ten cows grazing in the same pasture were killed, and it was found that nine out of the ten had general tuberculosis. He emphasized the importance of removing children from surroundings which exposed them to tuberculosis. The question of nostalgia should always be considered in such cases. In a recent epidemic of measles at the Foundling Asylum eighteen deaths occurred among the thirty-six children that had just been admitted; these eighteen had constantly fretted and were victims of nostalgia. Therefore, if these children were to be sent away they should not be sent so far that their parents could not see them occasionally. Because it had been proven that tuberculous milk could infect children, he advised that all milk be Pasteurized. The great treatment for these children he believed to be fresh air, good food, and rest. When confined to hospitals they did not do well, but when sent to the country they, as a rule, did very well.

Dr. WILLIAM P. NORTHRUP cited instances to show what the New York Board of Health was doing to prevent the spread of tuberculosis by the dissemination of knowledge regarding this disease. He did not wish them to underestimate the importance of the respiratory tract in the production of tuberculosis. In 125 autopsies on tuberculous patients, the bronchial glands were involved in all and the mesenteric glands in but one. Dr. Bowdich of Boston made 369 autopsies, and in only 1 per cent. were the mesenteric lymph nodes involved.

Dr. CHARLES N. DOWD said that among 100 cases of surgical tuberculosis which had been followed for years, it had been noted that only one patient showed evidences of pulmonary tuberculosis. Among these were cases of cervical tuberculosis, tuberculosis of the hip, of the axillary lymph nodes, etc., but in only one was there any pulmonary tuberculosis. Of this series of 100 cases, 87 were infected directly from the tonsils or pharynx. The last 1,000 cases seen at St. Mary's Hospital showed that 212, or 21 per cent., of them had tuberculosis. The distribution of these were as follows: 158 occurred in bones and joints; 40 in the lymph nodes; 5 in the genitourinary tract; 5 were perineal; 2 were lupus and 2 were of tendon sheaths. There had been 10 instances of infection of the iliac and femoral lymph nodes from foot wounds.

Dr. HAMILL of Philadelphia, in discussing the mode of infection, spoke of the possibility of the entrance of tubercle bacilli into the circulation without the development of localized lesions at the portal of entry. That such an occurrence was possible was shown by the frequency of cases of tuberculosis of the bronchial glands without discoverable lesions in the lungs or elsewhere. The same

possibility of cryptogenic infection through the gastro-intestinal tract was evidenced by the frequency of tuberculous disease of the mesenteric lymph glands, without the occurrence of intestinal lesions. While this kind of infections had not been shown to be of frequent occurrence, the possibility of their occurrence should be borne in mind in cases of tuberculous disease of deep-seated organs in which the mode of infection seemed obscure. The feeding experiments of Ravenel also aided in enabling us to venture the statement that infection through the alimentary tract might result in lesions far removed from the point of entrance of the infecting microorganism. That tuberculous lesions of the tonsils with secondary involvement of the deep cervical lymph glands might result from particles of infected food being retained by and absorbed from the tonsillar crypts has been definitely demonstrated. Tuberculous lesions of the intestines, together with tuberculous involvement of the lymphatic glands, as well as tuberculosis of these latter glands, without demonstrable lesions in the intestines, had been proven in like manner. It had been shown definitely by experimenters that tubercle bacilli could penetrate the intestinal tract and pass into the circulation without any evidence of lesions of any nature in the walls of the intestine. The bacilli once in the circulation might produce a generalized tuberculosis or might be deposited at some susceptible point and give rise to a localized tuberculosis. The bronchial glands being more susceptible to tuberculous invasion than the lungs, we might be justified in assuming that the bacilli having gained access to the lymph ducts were borne by them to the bronchial glands and likewise if the bacilli had gained access to the circulation they might be carried through the heart to the lungs and there gain access to the lymphatic channels by which they could be conveyed to the bronchial glands. Another possible mode of infection of the bronchial lymph glands through the medium of the intestinal tract was by the conveyance of the bacilli from the mesenteric glands through the medium of the thoracic duct to its point of junction with the efferent vessels of the bronchial glands, and their conveyance from this point by means of a reverse current to the bronchial glands. In view of these possibilities, we could not deny that many of the generalized or pulmonary tuberculoses which developed as a sequence to the various infectious diseases of infancy and childhood primarily had their origin in the intestinal tract. Bronchial lesions might remain latent for an indefinite period, and new foci might in the meantime become so far advanced as to entirely mask the point of original infection.

Dr. JOHN H. GIRDNER said that he had had occasion to observe people who lived in the mountainous regions of Tennessee and North Carolina, and he had been surprised to find what a large number of the children suffered from cervical tuberculosis, *i.e.* tuberculosis of the cervical lymph nodes. Young adults could be seen with the characteristic scars which had resulted from the breaking down and discharge of the tuberculous glands. This region was but sparsely settled, and there was but little opportunity for the infection to occur by way of the air passages. They lived upon the dairy products, such as milk, cheese, and butter. The cattle had been bred there for generations, and they were the so-called "scrub-mountain cattle." He believed these children had been infected for years by the milk of these cattle, and he had no doubt but that a large majority of them could be found to be tuberculous.

Peculiar Phenomena Accompanying the Growth of Bacteria in Media Containing Serum.—Dr. LIBMAN demonstrated a very marked example of coagulum production by a streptococcus in a medium containing glucose-bouillon with blood.

He also demonstrated some fluid which had been aspirated from the chest of a patient suffering from pneumonia. The fluid on withdrawal was light straw-colored, very slightly turbid, and contained pneumococci and a very few pus cells. After allowing the fluid to stand twenty-four hours in the thermostat it began to turn green. After forty-eight hours it was decidedly green and showed a very heavy, tenacious albuminous deposit.

Dr. Libman said he believed the observation was of interest in indicating that changes in fluids which are found to occur in the body might occur in a similar fashion by the growth of bacteria outside of the body.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held April 1, 1904.

DR. ROBERT T. MORRIS IN THE CHAIR.

Two Cases of Osteoplastic Craniotomy for Epilepsy.—Dr. H. D. COLLINS presented the following cases:

CASE I.—An Italian, fifty-seven years old, whose father was an epileptic, giving no specific history, was struck on the head and remained unconscious for several hours. He appeared to recover, but after five years he began to have headaches, which were followed by vertigo and convulsions. Two hours later he had another convulsion. He then had from two to seven convulsions daily, then an intermission of from several days to a week or two. On one occasion he had an unusually severe convulsion, followed by paralysis of the left side. He gradually recovered from the paralysis, and later these attacks of paralyses became more frequent and he showed less tendency to recover from them. It was supposed that there was some lesion at the site of the scar, probable hemorrhage in the deeper portion of the brain. An incision was made at the site of the injury, with the usual osteoplastic flap over the motor area. An extensive broken-down blood-clot was found, extending one and one-half inches into the brain substance. Since this operation, which was performed ten weeks ago, he had had no convulsions. The leg paralysis had improved.

CASE II.—A man who had been treated three years previously for cardiac trouble was taken with convulsions, followed by paralysis, which he attributed to an overdose of medicine. He had constant, dull headache, spasticity of the left leg, disturbance of the reflexes of the right arm, and some optic neuritis, which was supposedly of syphilitic origin. It was anticipated that operation would reveal meningitis or gumma. Some pulp-like substance was found. The interesting point in this operation was that during manipulation the bone flap was torn off, immersed in salt solution for some time, and then replaced. The union was good. It was ten weeks since this operation and there had been no convulsions.

Dr. ROBERT T. MORRIS had seen large pieces of bone replaced which united perfectly. The lymph circulation seemed to retain its vitality to an unusual degree. For the prevention of adhesions of the brain meninges after operation sterilized, chromaticized peritoneum could be used with better results than gutta-percha tissue, silver or gold.

Dr. PECK related the case of a boy who had shot himself through the roof of the mouth eleven years previously, the ball passing out through the frontal bone. He became subject to epileptic fits, and craniotomy was performed over the scar. A cyst was found in the frontal lobe. The epileptic seizures disappeared for about two months and then gradually increased in frequency.

Dr. Collins, in closing, said that he had not claimed cures, as in these cases epilepsy was likely to recur. The points of interest were the large surface of brain exposed and the large piece of bone that was removed and then replaced so successfully.

A Case of Fracture of the Zygomatic Arch.—Dr. WARREN S. BICKHAM said that he had had a collision in which he had sustained such a fracture. In searching literature on the subject of zygomatic fractures he had found very little. Scudder only mentioned the subject once and then only incidentally. In Beck there was only ten lines in regard

to the fracture and nothing as regards its treatment; in Stimson there was one and one-half pages in conjunction with malar fractures and a statement to the effect that it was seldom that they could be replaced. After the accident he was very much stunned, the noise was tremendous, due to the proximity of the middle ear, and he could not move his lower jaw. Dr. Matas gave him one-quarter of a grain of morphine and, on examination, found that he could put his thumb between the fragments. Under a general anæsthetic, he cut down on the arch; with a Hagerdorn needle he penetrated one inch above the zygomatic arch and, carrying the needle deeply into the temporal fossa, came out one-half inch below the arch. The needle carried silver wire, and on traction the bones were drawn into place. To keep them in position an ordinary microscopic slide was placed over the malar and temporal bones. A dentist made a vulcanized rubber plate, which was introduced in place of the slide on the following day. In such fractures Dr. Bickham suggested putting a dressing of collodion or rubber adhesive underneath, as this would prevent the deformity that was liable to occur.

Dr. JOHN F. ERDMANN considered this an ingenious device, which ought to be followed by good results.

Dr. MARTIN W. WARE had had two cases of fracture of the zygomatic arch and had only strapped the parts firmly together. His experience had led him to believe that no radical operation was necessary. If there was a marked depression, it might be well to resort to such an operation.

Dr. Bickham said that the procedure was so simple that it could easily be employed wherever there was any prospect of deformity, and should certainly be employed in compound fractures.

A Case of Hypertrophic Papillary Colitis; Right Inguinal Colostomy.—Dr. A. A. BERG presented this case. The patient had presented himself for treatment in November last, after suffering for nine months from frequent evacuation of blood and mucus from the bowels; he had lost thirty pounds, and was much weakened. Rectal examination showed a large number of villous growths. The sigmoid flexure and *caput coli* were distended and there was considerable tenderness. A right inguinal colostomy was performed. The anterior wall of the cæcum was sutured to the peritoneum. The opening made was no larger than for an appendectomy. The results, however, had not been brilliant, the bowel was washed twice daily with silver nitrate solution, and while the patient had gained strength, the bleeding began as soon as the washings were discontinued. A number of the villous growths still persisted, and the question that now presented itself was whether he should resect the entire colon and sigmoid flexure.

Dr. JAMES P. TUTTLE said the pathology might be interesting, as the growth might be partially epithelial or it might be an adenoma, in which case it might have the same degeneration eventually. If the case was one of papilloma, prospects of cure were remote unless the growth was removed, and in such cases the ascending and transverse colon was usually involved. Washings with silver nitrate, iodine, or astringents might allay the symptoms somewhat, but were not very effectual.

Dr. R. H. DAWBARN asked Dr. Berg if he had any objections to the technique of Dr. Weir—the appendix operation. The condition of the appendix must decide the choice of methods. He irrigated with a glass cannula, and if there was slight inflammation he waited until it subsided before introducing a soft rubber catheter. He secured the best results by that method and would advise its adoption accordingly.

Dr. ROBERT T. MORRIS thought that if we used Weir's method the lymphoid layer might not swell fully. If the appendix was amputated near enough to the cæcum the method might be desirable.

Dr. Berg, in closing, said that the affection was not specific; that there were a number of small papillæ, but we could not decide whether they would become malignant or not. If we feared malignant disease we should remove the colon. He thought Dr. Weir's use of the appendix good if that organ was healthy, but it seemed a half-way procedure. In flushing the bowels we wanted an opening large enough to admit a 26 or 28 Fr. catheter. If the *caput coli* was used there would be no more inconvenience if it became necessary to establish an artificial anus. Regarding the patient's hernia, he had it on getting up, and a pad had been applied to retain the hernia and keep the piece of gauze over the wound.

Dr. Tuttle said that, if the appendix was drawn well up into the wound, it could be readily dilated to such a size as to give admittance to a 28 Fr. catheter.

A Case of Movable Kidney in a Child.—Dr. A. ERNEST GALLANT presented a girl, fourteen years old, who had consulted him in December, 1902. She was very much run down and had lost much in weight. She had attacks of vomiting, severe pains in right side, and had never menstruated. Examination showed a floating right kidney; the pylorus reached to the umbilicus. She had been fitted with a corset; it was just like an ordinary corset except that it was long and had been fitted with the patient in the recumbent position with hips elevated. The lower part was tightly laced and the upper part left loose, giving full liberty to lungs and stomach. Since wearing the corset she had gained twenty pounds in weight, had grown four inches, and the kidney no longer came down and she no longer had the severe attacks of pain. She now menstruated.

Dr. ROBERT H. M. DAWBARN asked why we should take it for granted that a case of nephroptosis was necessarily accompanied by a gastroptosis. It had not been his experience that one was a necessary concomitant of the other.

Dr. ROBERT T. MORRIS said he had observed two classes of cases, in one of which the kidney alone wandered, and in the other, the liver began to descend about as soon as the kidney; the pylorus also descended.

A Case of Tenorrhaphy and Neurorrhaphy of Flexor Tendons and Median and Ulnar Nerves.—Dr. WM. A. DOWNES presented this case. A girl, twenty-three years old, in falling thrust her hand through a glass door, causing a very extensive injury above the wrist, dividing the flexor tendons and median and ulnal nerves. The wound was so severe that the hospital interne would not attempt its repair and she had waited over night for attention. The tendons and nerves were sutured with chromicized catgut and the wound healed by primary union. In four months she practically regained sensation of the ulnar nerve, in eight months of the median nerve, and, at the end of one year, function was nearly restored and sensation was entirely regained. She could write, sew, and play the piano, though the cosmetic effect was not all that could be desired.

A Case of Fibroma of the Popliteal Nerve.—Dr. WM. A. DOWNES presented this case. A woman, aged forty-nine years, said that fifteen years ago she began to have pains in the right leg and foot. They would continue for a day or two and then might not recur for four, five, or six weeks. About seven years ago, during pregnancy, the trouble was aggravated, the leg became discolored, and she had difficulty in using it; but it became better after her labor In March he had removed a tumor from the internal popliteal nerve, a fibroma of the nerve sheath; it was centrally situated, and the nerve fibers could be seen stretching over it longitudinally and completely covering it. It was this that made the case especially interesting. It was peeled out without injury to the nerve. There were no nerve elements in the fibroma. No other evidences of fibroma were found.

Dr. ROBERT H. M. DAWBARN said that he had learned that in tendons and nerves severed by a dirty instrument we should dissect out the ends of the sheaths; a tendon could get along without its sheath. If the dividing force were infected with streptococci we could not depend uopn

any rapid mode of disinfection. He sewed the tendons at the time of operation, but did not tighten; then the wound was packed with gauze wrung out of a bichloride solution, and at the end of twenty-four hours the work was completed.

Dr. ROBERT T. MORRIS suggested that this was another case in which sterilized peritoneum could be used with advantage in separating the tendons.

Dr. MARTIN M. WARE said the regeneration of tendons emanated from the sheaths, and if the sheath was removed function necessarily would be impaired. To obviate this he permitted the tendon-ends to merely approximate one another and then placed the sutures through more remotely from the ends, leaving the middle part open to avoid infection.

Recurrent Sarcoma of the Brain.—Dr. FREDERIC GRIFFITH presented this case with the following history: J. S., was a Hebrew aged forty-one years. The man's history had been negative until July, 1903, when a small papillomatous growth upon the scalp attracted attention. His physician at this time advised removal, which was refused until in September, when an extensive operation for removal of the rapidly growing and extending growth was performed at one of the large city hospitals, diagnosis of sarcoma of the dura having been confirmed. Return of the growth became manifest in November, since which time until the present *x*-ray treatment, three times a week, also injection of Coley's toxins in the back and directly into the growing mass, had been employed with no effect. The growth seemed to cover the whole top of the brain with elevation of the vault of the skull. Involvement of the temporal region upon the right side was present. The patient suffered but little discomfort considering the great size of the cancer. Aside from slight contraction of the pupil of the right eye and headache with discharge of fluid through the large cranial opening upon the right posterior segment of the skull the patient suffered but little inconvenience.

Auto-retraction and a Method for Facilitating the Dissection of Ruptured Abscess Gland Cavities Occurring During Operation for Removal of Such Glands from the Neck, with Cases.—The histories of the cases presented were as follows: M. S., a gardener, aged forty-three years, had had enlarged and suppurating cervical glands over twenty years upon both sides of his neck. Operative treatment undergone in Ireland for the cure of those upon the right side consisted of incisions with cauterization. Three years ago he underwent operation, for removal of the chains of enlarged glands upon the left side at the New York Hospital. A dissecting operation lasting over a period of five hours in an attempt to clean out the neck spaces, was performed. The patient was operated upon by Dr. Griffith upon March 25 for a new growth of glands which had enlarged about the sites of the old operations. Cocaine anæsthesia, using a ½ to ¼ per cent. strength solution of cocaine, hydrochlorate in warm, weak soda solution, was employed. The patient was shown, the wounds having healed, in demonstration of a procedure which was used to anchor the gland mass, which, while deeply situated, was very movable. By having the patient open his mouth, Dr. Griffith was enabled to complete the dissection and remove the gland mass through a comparatively small incision. When operating alone, as in this case, the problem of how to retract and dissect at the same time may often be readily solved by employing the method described.

The second case shown was H. K., aged eighteen years, a packer, who was operated upon for enlarged cervical glands by Dr. Griffith in March, 1903. A bilateral operation under cocaine anæsthesia was done. In January, 1904, the patient returned with a new growth of glands upon the left side. He was shown at this time for the purpose of describing a method of dissecting gland masses which have gone on to abscess formation and ruptured during operation. By stuffing the evacuated sac with gauze or cotton Dr. Griffith had been enabled to make clean dissection, the contour of the mass being retained. Local anæsthesia in the form of the weak cocaine solution was employed during the operation.

Dr. DAWBARN said that he had found recurrence of tuberculous glands in the neck after careful operation to be a rarity, and would advise the members of the section not to hesitate to sacrifice the sternocleidomastoid muscle, if need be, in performing a complete operation.

Dr. Griffith replied that a good surgeon had worked five hours in an endeavor to be thorough.

"Pro and Con Nephropexy."—Dr. A. ERNEST GALLAUDET read this paper and said that the real art of modern surgery lay in knowing when *not* to operate. The unsatisfactory results obtained by many leading surgeons had led them to discourage nephropexy for the relief of prolapsed kidney; the 150 or more methods of operating, and the rapidly increasing number of observers who of late have accepted Glenard's theory that a movable kidney was but an index of a more general ptosis of several of the intra-abdominal viscera, notably the stomach, colon, liver, and spleen, compelled a more careful consideration and differentiation of the symptoms induced by each, in order to arrive at a satisfactory plan of treatment.

Symptoms.—The symptoms produced by a prolapsed kidney were characterized by their acuteness, remittent from day to day or less often, rapid subsidence after the kidney had been replaced and the patient maintained in inclined dorsal posture, the early return of the symptoms when, soon after, the patient resumed the upright posture. Pain originated in the hypochondrium, extended through to the back, and down the loin, rapidly becoming very intense, with distension on the same side of the abdomen. Nausea and vomiting soon came on and continued even after the stomach was emptied. Constipation, or diarrhœa, with dark or light stools, might be present. The urine was scanty, dark, acid, with or without albumin. The pulse was rapid, small, and of high tension. Hydronephrosis or jaundice, or occasionally hæmaturia, intervened, and the patient was seized with a maddening desire to remove all clothing and lie down. Within two or three hours or less the pain would subside. The patient then may rise, dress, and, barring some tenderness along the loin, feel as well as ever. She might pass large quantities of urine. These Dietl's crises might recur from day to day, the severity depending upon how long a time intervened before she could lie down. He said that jaundice was most often met with in women who had recently borne children, or multipara, with lax, flabby abdominal walls. The lower half of the right kidney presenting a fixed mass projecting below the chondral border, easily mistaken for a distended gall-bladder or the lower edge of the liver. These attacks resembled those of stone in the common or cystic ducts. The kidney could be gradually replaced by gentle manipulation, and when the foot of the bed was raised ten inches the severe symptoms soon subsided and the jaundice rapidly diminished. Should the patient sit up for a few hours without abdominal support the attack would soon recur with all its former severity. The gastrointestinal group of symptoms, on the other hand, were notable in that they appeared slowly and insidiously, ran a chronic course, were seldom, if ever, relieved by ordinary means, and were the common to gastrointestinal atonia, viz., chronic gastritis with dilatation or ptosis of the stomach and colon, food retention, fermentation, epigastric and cardiac pain, loathing of food, etc.; each and all pointed to the stomach directly as the source of discomfort. Malposition of the intestines led to chronic constipation, followed by auto-intoxication paralyzing muscular, mental and moral activity, loss of flesh and strength, and a condition of chronic invalidism, often characterized as neurasthenia.

Conclusions.—In endeavoring to answer the question "To operate or not to operate," he formulated the following conclusions: That, as the large majority of observ

now agreed with Glenard "that the movable kidney is merely an incident in a general ptosis, and the symptoms referred to the kidney are much more liable to be the result of the intestinal displacement, as is also the case in troubles caused by deformity or abnormal mobility of the spleen, liver or kidney and dilatation of the stomach;" and as symptoms due to kidney motility could be differentiated from those of gastrointestinal origin, nephropexy was justifiable on displaced kidneys after operations on that organ or its ureter for any cause. Nephropexy, hepatopexy, splenopexy, gastropexy, gastroplication, suture of the recti, etc., might occasionally be indicated; but multiple operations on the same patient were not to be recommended. The chief cause of failure after nephropexy was that the kidney could not be fixed high enough above the waist line to avoid the constriction of the waistbands and drag of the clothing, and ought not to be employed when the kidney laid above the waist line. Nephropexy could but relieve the symptoms due to kidney instability, and in order to overcome the general ptosis, Dr. Gallant, in 1901, evolved "a new principle in the adaptation of the ordinary corset for the treatment of Glenard's disease," viz.: Visceral replacement, by gravity, with patient in the dorsal position. Support of the replaced viscera by a made-to-order corset, constructed from measurements taken while the woman was lying down, laced with two sets of strings, from above down, put on while in the semi-prone posture and fastened from below upward. By this plan the organs were supported *in situ* and could not fail while the corset was on and fit snugly enough over the suprapubic area, loosely above the waist line and curving gracefully at that point. With the support of all the viscera, nephropexy for movable kidney, per se, was rarely indicated, multiple operations could be avoided, and the woman placed in a curable condition.

Dr. A. H. GOELET said that the position of the kidney after fixation depended upon the suture at the time of operating. When suspension sutures were used it was an impossibility to get the kidney above the waist line. He sutured through the fibrous capsule and attached the kidney to the structures of the back. The sutures were below the center of the kidney and at the upper angle of the wound. If the kidney was abnormally large, care must be taken not to anchor it too high up, especially the right kidney. As to indications for fixation, Dr. Gallant admitted that operation was necessary when there were serious conditions, as hydronephrosis, nephritis, etc., and he wished to emphasize the fact that he had better results by operating early, before such serious conditions occurred. He had operated upon 179 cases with only one failure in securing permanent fixation of the kidney. This failure occurred because an abdominal section was also required, and he first fixed the kidney, then a week or so later did the abdominal section, and the vomiting caused by the anæsthetic loosened the kidney from its attachment. It was not true that nephritis was accompanied as a rule by general prolapsus. He thought belts and corsets were useful after operation and before there was general ptosis. In 75 per cent. of the cases there was nephritis or pyelitis, and, in these cases, a corset seemed to aggravate these affections.

Dr. ROBERT H. M. DAWBARN said that if belts or corsets were used they should be put on in the recumbent position, but he would not like the Surgical Section to go on record as approving such treatment. His objections to corsets were that they encouraged the too common tendency of women to auto-intoxication, as they interfered with peristalsis and constipation resulted, and this threw additional excretory work on the kidneys which might be a factor in the causation of nephritis.

Dr. GALLANT closed the discussion.

An Attachment to Bennett's Inhaler, for Pharyngeal (Crile's Method) and Tracheal Administration and for the Ethyl Chloride-Ether Sequence.—Dr. VICTOR C. PEDERSEN made this presentation. The same presentation had been made before the Section on Laryngology and Rhinology.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held March 10, 1904.

DAVID BOVAIRD, JR., M.D., CHAIRMAN.

Presentation of a Case of Recto-vestibular Fistula in an Eight Months Old Baby.—Dr. SARA WELT KAKELS presented this patient. On November 25, 1903, the child was brought to the dispensary suffering from an enteritis, numerous undigested stools of bad odor being passed. There was present an umbilical hernia and a considerable number of adenoids. The physical examination of the abdomen and thorax revealed nothing abnormal. The vulva was found to be covered with a mucopurulent discharge, and, on inspection, there was found a well-formed large and small labia, as well as a normal anal orifice. A funicular depression was noted in the vestibule of the vagina, directly below the hymen, and this lead to a fistulous duct which communicated with the rectum. A probe was readily passed. The fistula was lined with mucous membrane and fecal matter passed through the vagina. The perineum was short and low. No gonococci, diphtheria, or tubercle bacilli were found in the vulvar secretions. There was no history of trauma.

To explain the development of this anomalous condition the doctor referred to the early embryological conditions, and stated that the common cloaca (the common opening of the intestinal and urogenital passages at the caudal extremity of the embryo) persisted until after the fifth week, while the separation of the cloaca into the genitourinary sinus and the anal orifice, as well as the formation of the perineum, took place between the seventh and tenth week of embryonic life. According to certain teachings she said that this was effected by a downward advance of the septum Douglasi, or the rectovaginal septum. This theory was rejected by Reichel in 1888. After he had observed this anomalous condition in an adult woman he made careful researches on human embryos, and was led to believe that the perineum was not formed by the advance of the septum rectovaginali, but was mainly effected by a median coalescence, forming anal protuberances. These protuberances, which originated from the ectoderm, advanced and united in the median line, and they also grew upward and united with the descending septum Douglasi. The raphe perinei remained as a remnant suggestive of this union. Accordingly it was supposed that this anomalous condition was caused by an incomplete union of the anal protuberances with the septum Douglasi, and therefore was an error in development. In the literature but three analogous cases were to be found, one reported in 1863, another in 1886, and the third in 1890.

Report of Case of Hydrocephalus Treated by Drainage.—Dr. ALFRED S. TAYLOR reported the case of an Italian child that was fourteen months old at the time of operation. The family history was one that gave no idea as to the cause of the hydrocephalus. This was the fourth child, was a breech presentation, and so much force was used in extracting it that the child received a fracture of the leg. The child never had convulsions or serious illness during its early infancy. When five months old the parents noticed the head gradually growing larger, and from then until the child was presented for treatment seven months later the head grew steadily. Just preceding the operation the physical examination showed a well-nourished child, with limbs well developed and reflexes normal. The child was thirteen months old when operated upon. The patient had sufficient strength in the neck to roll the head about when on the bed or on the floor. The head was very large, and the anterior fontenelle was wide and bulging. The eyes markedly protruded, and the sclera was visible around the iris. For nine months previous to operation the child had been under the care of a pediatric physician, and during that time the head had increased from 49 to 59 cm.

On March 13, 1903, the operation was performed under chloroform anæsthesia. An osteoplastic flap about two inches in diameter was turned down with its hinge over the base of the mastoid bone. In the lower part of the dura thus exposed a semicircular flap, with base downward and about one inch in diameter, was made. The operation was so planned that the second tempero-sphenoidal convolution protruded through the opening, and through this was inserted a slender aspirating needle, inward and slightly upward, until it entered the ventricle, when clear fluid spurted out. Only a very small amount of fluid should be allowed to escape in this way. A drain was then made of half a dozen strands of No. 1 forty-day chromic catgut, and arranged in a spiral, made half an inch longer than the thickness of the brain substance. Around the shaft of the drain was rolled Cargyle membrane. The drain was introduced with narrow-bladed thumb-forceps into the ventricle along the tract made by the aspirating needle, and the tip was permitted to project from one-quarter to one-half an inch into the ventricle. The free loops of gut were slipped under the dura between it and the brain surface in different directions, but slightly downward toward the great lymph spaces at the base of the brain. A sheet of Cargyle membrane was slipped between the dura and the catgut loops to prevent adhesions. The dura was then sutured with catgut, the osteoplastic flap replaced and held by chromic catgut sutures, the deeper soft tissues were united by catgut, and finally the skin with silk. Over the whole sterilized dressings were applied with firm pressure. The wound healed by primary union. The reaction was moderate, the temperature on the second day rising to 103°, but the child did not appear to be particularly sick.

The interesting feature following this operation was the effect upon the head. Before operation the circumference was 59 cm., and ten days after the operation, when the dressings were first removed, it was the same. The child was perfectly comfortable. After the forty-fourth day two sets of measurements were taken and lost. About the sixty-eighth day there was a noticeable asymmetry of the head, the right side being flattened. On the eighty-second day this asymmetry was even more apparent, and the circumference of the head was 55.5 cm., a lessening of 3.5 cm. since operation. On the one hundred and fifth day the head increased to 57 cm. On the two hundred and fifty-fourth day the head was 61 cm., and on the three hundred and twenty-sixth day the circumference was 61.5. During the seventy-two days preceding this last inspection the head had grown .5 cm. The fontanelle was soft and retracted. The eyes were intelligent, and the exophthalmos had disappeared and the child was playing in the crib.

Dr. Robert T. Morris said that the report of Dr. Taylor's case certainly was one along the lines of progress and pointed to a very interesting field for observation. In 1885 Kirke proposed draining the fluid into the connective tissue, but obtained no good results. Seen later did the same, separating the tissues of the scalp, but all was done external to the scalp. Both these experiments were failures. Dr. Morris experimented with spinal drainage. In 1821 Bernard reported fair results from compression. His report was followed by reports from various experimenters and then further work was abandoned for a time, all operations falling into disrepute. He said that about 1884-85 Morton suggested the use of a fluid consisting of iodine, iodide of potassium and glycerin. At this time Dr. Morris operated upon two Italian patients, but lost track of both. In 1873 the *Irish Hospital Gazette* published a successful case, the cure being produced by the use of seton. In 1890 there were 5 reported cures by seton. In 1834 Conquest reported 9 cases that were drained, 1 was cured and 8 died from sepsis. Blackman in 1854 reported 69 cases with 53 deaths and benefit or cure in the remaining 16 cases. In these cases he believed that if the fluid could be removed cure was possible.

As a bit of negative testimony Dr. Morris reported the following: Recently Dr. Chapin sent him a case of hydrocephalus in which he planned to turn the temporal vein into the lateral ventricle for drainage. This was accomplished, the temporal vein being connected with the ventricle by a small silver tube. Curiously enough he found a reason for his failure to get the desired result. The hydrostatic balance was so perfect that the fluid would not escape from the ventricle while the connection was intact with the silver tube. In further considering the mechanical features of the case he felt quite reasonably sure that if this mechanical obstacle of a collapsed vein could be gotten rid of, he would be able to drain the ventricle into venous channels.

Dr. Henry Dwight Chapin thought these experiments were very valuable and interesting, inasmuch as there was so much confusion regarding the causes of failure in the treatment of hydrocephalus. He had tried compression and found that it was not at all efficacious.

Dr. Churchill Carmalt mentioned five cases treated with and without drainage. Case No. 1 was aspirated every other day for seventy days with apparently no effect upon the growth of the head. The aspiration was continued until the child became pale. The head would diminish in size about ½ cm. and two days later the loss would be regained. After being treated fifty days the head increased rapidly in size and the child later died of hydrocephalus without infection. Case No. 2 was aspirated four times. This was four years ago; the child lived two years and was then lost sight of. Case No. 3 was opened and drained and died of infection. Case No. 4 was opened and drained and did well for two weeks. The drainage was then removed and the child died one month later from hydrocephalus without infection. Case No. 5 was opened and drained and did well for one week or ten days and then died from hydrocephalus.

Of five cases he had seen one was in a child who had, when first seen, a spina bifida; one year later the child was returned with a marked hydrocephalus, the head measuring 45 cm. Although there was no history of syphilis, the child was given mercury and, at the end of one year, was quite well, and to-day was in the office talking and walking. Two other patients died of hydrocephalus and one got well without any treatment. From time to time one met with cases of hydrocephalus which seemed to recover without operation.

Dr. A. Ernest Gallant wished to mention an experiment he had recently made. A seven-month child, born November 11, 1903, was his subject. The mother had had two previous miscarriages, having been pregnant three times during the year. The father was said to be syphilitic. When the child was first seen the head measured 13 inches in circumference and, from ear to ear, 9½ inches. He said that in literature the statement was made that better results were had in syphilitic children. Various methods of treatment had been tried, but those most successful were those in which catgut drainage had been resorted to, passing the drain directly through the scalp into the ventricle, but the complaint had been made that the catgut absorbed too soon, thus stopping the drainage. Therefore, he concluded that silk-worm gut would do better. A large hypodermic needle was introduced into the ventricle, and strands of silk-worm gut was passed into the ventricle and drainage was fairly active. Drainage continued from January 31 to February 13. He then thought that if something larger could be introduced the patient would do better, so he took a fine silver wire and twisted four strands of it together and introduced this through the trocar, fastening the end without by means of a split bullet. This was left in until March 2, when the child died. If the doctors had changed the dressings he believed the child would have lived. The parents had charge of the dressings and believing the child would be idiotic, didn't want it to live. There was no sepsis. The child was placed on iodides, one grain, then two, and

then three grains being given with each feeding, there being eight feedings a day.

Dr. DAVID BOVAIRD, Jr., said that he had been impressed with the remarkable changes in the brain tissues at autopsy in these cases of hydrocephalus, whether drained or not, and he asked Dr. Morris what he meant by a cure.

Dr. Robert T. Morris said that the report was not tabulated and, although it covered a number of years, it was not a clear one. The so-called internal cases were not separated from others. Each case had been referred to as recovered, but the character of the recovery was not given. On careful analysis of the papers, though, he thought cure meant, in a large proportion of the cases, that the secretion had ceased, that the hydrocephalus had not increased, that the mental faculties had developed to a greater or less extent and that the patients had lived.

Dr. GALLANT said that it was not necessary to have the head diminish in size to any extent so long as the tension could be relieved. The important point was that if there was no pressure exerted upon the brain it would develop, other things being equal.

Dr. TAYLOR was interested in what Dr. Morris said regarding draining the ventricle, and wondered if the ventricle was drained into the vein as proposed by Dr. Morris what would happen when the child cried or strained; would the back-pressure within the venous system cause any difficulty with the cerebral pressure? He did not think that aspirating would accomplish anything, because the fluid would be thrown out more rapidly than it could be removed. Again, while infection may not be carried in through the punctures he said that certain elements might be carried in which would lead to a hasty death. He referred to a series of nine cases reported in which accidents had occurred with fracture of the skull, and fluid passing from the ear or nose with resulting cures of the hydrocephalus. He did not believe any external drainage could permanently cure a case because of the danger of infection. If one drained rapidly there would be a rise of temperature and convulsions. Dr. Keen a few years ago had drained the ventricle rapidly by means of a rubber tube, and this was accompanied by rise of temperature and convulsions. Normal saline solution was then injected into the ventricle with a disappearance of these symptoms. He repeated this several times. He said that drainage should be slow, just enough to take off the excessive pressure. One should remember that any damage to the brain tissue can never be repaired, and, therefore, one could only attempt to remove the excessive pressure and keep the child in as good a condition as possible. Treatment to be effective should be begun as soon as the diagnosis was made.

The Limitations of Chemistry in Infant Feeding.—Dr. HENRY DWIGHT CHAPIN read this paper, and said that the past few years had been noted by an attempt to put artificial infant feeding on a scientific basis, a thing greatly to be desired. The European method of determining the number of calories used by an animal, and then giving a quantity of food which, when burned, yielded the same number of calories, had been tried in infant feeding. This method of animal nutrition was not looked upon favorably for adult feeding by modern investigators of the problem of nutrition; they had found that much better results attended viewing an animal as an organism endowed with food preferences, than as viewing an animal as a mere machine in which any food was transformed into heat and energy. In America there has been a tendency, or rather an attempt, to place artificial feeding on a purely chemical basis. The scheme of food preparation, based exclusively upon percentage composition of milk, was now known to have been based on incorrect data. If one attempted to adjust the percentages of fat, proteid, carbohydrates, mineral matter and water to suit the infant, the question naturally would arise, what constituted suiting the infant? Was it to suit its digestion or its general nutrition and development? Modern investigators into the problem of nutrition had come to the conclusion that preferences for certain foods was a very important factor in feeding, and could not be ignored if the best results were to be obtained. It was a matter of common knowledge that there were different forms of fat, and there were also different forms of proteid. The only feature that all proteids had in common was that they contained nitrogen in fairly uniform quantity. 15 to 18 per cent. He said that Van Slyke and his co-workers had their efforts crowned with the brilliant discovery of some of the chemical processes that took place in the formation and digestion of the curds formed from casein. In brief, these processes were that the rennet of the stomach converted the casein of milk into a curd or paracasein, which then formed a definite compound with hydrochloric acid as chloride or bichloride of paracasein, and then, and not till then, would pepsin attack the paracasein. He said that most investigators into the problem of animal nutrition had found that the peculiarities of the species and individuals must be carefully considered or good results in feeding could not be obtained. After finding what kind of food was best suited to the animal's appetite and digestion, chemistry stepped in and aided in determining the quantity necessary to maintain the animal or enable proper growth to be made. Such investigators have shown that there were minimum quantities of different kinds of food which were absolutely necessary for the well-being of any particular animal or species of animal, and a chemical analysis would often be of great value in explaining the lack of proper development or failure to do well. He said that in practice there was little call for frequent analysis of food; that after the minimum food quantities had been determined for a particular species of animal, a general knowledge of the composition of foods and a rough method of calculating the nutritive value of the food was about all that was necessary. Each animal must be fed according to its peculiarities.

In infant feeding it had been found by experience that milk must be the basis of food, as milk developed the digestive tract. Milk diluted more than three times was not a safe food for continuous use for infants, for it did not contain enough proteid or tissue building material. Diluted condensed milk required from 2 to 4 per cent. of fat, and 4 to 6 per cent. of carbohydrates along with tissue builders to ensure proper growth. He said that it should be borne in mind that some persons or animals appropriate their food to better advantage than others. There was no universally applicable food for man or beast, and the successful feeder was the one who got the infant to take some suitable food, and then adjusted the ingredients so that they were in sufficient quantity to carry on the normal chemical changes that took place in the body and allowed storage of tissue other than fat and, at the same time, produce proper functional development.

The Treatment of Tracheotomy Wounds in Diphtheria.—A. E. Jones says that the main lines of treatment are the following: (1) The wound should be kept as aseptic as possible. It should always be covered with a double layer of aseptic gauze, which can be conveniently fastened at one corner to the sternum either by a spot of collodion or by a strip of Unna's zinc strapping. (2) The tube should be removed at as early a date as possible, more especially if any of the laryngeal cartilages be injured. One can usually take out the silver tube after twenty-four hours, and if another tube be required later on for a few hours more, a rubber one should be inserted. (3) Every effort should be made to calm and reassure the child, and in some cases the administration of bromide of potassium is of use in very excitable children. (4) The only contra-indication to the use of heroic measures if the wound does not spontaneously close is a poisoned and dilated heart; when this is present, as it was in the above case, one has to be very careful and proceed at intervals.—*British Journal of Children's Diseases.*

New Instruments.

A NEW ANÆSTHETIC INHALER.

By RICHARD E. MERCER, M.D.

The inhaler consists of two cylinders A and A′, covered by two caps B and B′, into the center of which are inserted tubes C and C′, which project about half an inch on each side of the caps. The inner projections prevent an excess of chloroform or ether from being spilled if the cylinders are inverted. The outer caps have graduated openings D and D′, which control the admission of air to the gauze inside the cylinders, and are regulated by turning caps from which an index-pointer projects to the index on the rim of caps B and B′. At the base the cylinders are connected by a T-shaped tube E which leads to the rubber mask M, through tube

H and inlet valve I (this valve does not show in the cut). It has another valve O which controls the admission of air directly to the mask. The nipple G (guarded by a little screw-cap) is for the attachment of tubing X for connection with oxygen or nitrous oxide cylinders.

The mask M is of soft rubber, shaped to fit any face without undue pressure. It has two openings, one the inlet guarded by the inward opening valve I, the other the outlet by the outward opening valve O.

The valves are very simple in construction, consisting of a thin piece of flat hard rubber held in place by small crossbars, and can be easily replaced when necessary.

The inhaler is simple, easily cleaned, and can be sterilized by boiling. The appliance is made by Geo. P. Pilling & Son, Philadelphia.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending April 30, 1903:

	Cases.	Deaths.
Measles	1398	46
Diphtheria and croup	409	62
Scarlet fever	419	26
Smallpox	6	...
Varicella	44	...
Tuberculosis	490	199
Typhoid fever	40	6
Cerebrospinal meningitis	30	70

Local Asphyxia of the Extremities with Gangrene of the Phalanges and Sclerodactylitis.—Balzer and Fouquet describe this case. The patient was a man of thirty-two years, non-syphilitic, but afflicted with pulmonary tuberculosis. At the age of twenty-eight he began to suffer from pain in the upper extremities, followed by gangrene of the fingers. The end phalanges dropped off. The stumps formed cicatrices very rapidly. All of the digits were affected, excepting the thumbs. The fingers were, besides, the seat of cyanosis and scleroderma. The sensibility was normal. The nose and the ears were intact.—*Archives Generales de Médecine*, March 15, 1904.

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S Marine Hospital Service, during the week ended April 30, 1904:

SOME CHARACTERISTICS OF STEGOMYIA FASCIATA WHICH AFFECT ITS CONVEYANCE OF YELLOW FEVER.*

By H. R. CARTER, M. D.,
BALTIMORE, MD.
SURGEON U. S. PUBLIC HEALTH AND MARINE HOSPITAL SERVICE.

It is not proposed here to go into the life history of *Stegomyia fasciata*, but simply to call attention to such of its peculiar characteristics, differentiated from mosquitos in general, which seem especially to influence its rôle as a conveyer of yellow fever.

Here let me premise that only this species of the genus Stegomyia has been shown to act as a host for the conveyance of yellow fever to man. Following the analogy of malaria and Anopheles we would expect that the other Stegomyiæ, of which there are many, or at least some general subdivision of the genus most closely allied to this species, would act in like manner. No attempt to determine this point has been reported. Stegomyiæ, other than Stegomyia fasciata, must then, with our present knowledge, be regarded with suspicion as probable hosts for yellow fever, but against whom the charge is not proven. Similarly, analogy is against any other genus being able to act as host for the micro-organism of yellow fever.

Of the characteristics of Stegomyia fasciata which affect its rôle as a conveyer of yellow fever, the first that we will consider is:

Distribution.—Obviously this is all important. Localities in which this mosquito breeds and feeds on man are "infectible localities" and in them yellow fever is a communicable disease and will spread if cases be introduced without precautions. Here we must note that this form has been of special interest only a short time, and that the account of its distribution is necessarily lacking in completeness; and the fact that it has not been reported from a particular district, unless we know that careful and well planned search has been made, is not conclusive that it does not occur there.

All writers agree that it is widely distributed in tropical and subtropical countries. Theobald, in a recent monograph in *Tropical Medicine*, states that it is found generally between 43 North and 43 South. In North America, at least, we shall find its original habitat is much more limited, and that even where introduced it does not make good its permanent settlement beyond North Lat. 38 or 38½. The writer above quoted gives its Old World distribution as follows:

Asia: India generally, coast and interior, Malay States, Farther India, Celebes, New Guinea, Japan, and Palestine.

Australia: Queensland, New South Wales, Victoria, and South Australia (very abundant).

Africa: West coast from Senegambia to Nigeria, East coast from Port Said to Durban, Pretoria and British Central Africa generally, and Uganda (as it has been found at the Savannah Quarantine Station aboard a vessel direct from Cape Town, this district also must harbor it).

Europe: Spain, Portugal, Italy and the Mediterranean Islands to Cyprus; especially abundant at Gibraltar.

Oceanic Islands: Fiji, Mauritius and Seychelles.

It has not been reported in the Philippines, a matter of interest to us, nor on the Chinese coast, although other forms of Stegomyia are found in both places, and with the communication between these places and Japan, India and the Straits Settlements it seems improbable that this form has not been introduced, and probably it does exist in both countries, at least in the coast cities.

Van Dine of the Hawaiian experiment station reports Stegomyia fasciata as abundant and generally distributed over those islands, having been introduced in the last generation.

Obviously the wide distribution here noted in countries hitherto free from yellow fever, makes it extremely important not to introduce men sick of yellow fever into them. If other forms of Stegomyia can also convey yellow fever, the territory to be guarded becomes considerably increased.

In America this form has been reported from a number of the West Indian Islands and East coast towns in Mexico; Central America and South America as far south as Montevideo. It has been so generally reported where it has been looked for in these limits that it may be regarded as generally present in the coast towns from the Rio Grande to the La Plata.

It is also found at Panama and at Guyaquil on the west coast. But few reports, and I think but few examinations, have been made of the interior towns. It has been found in some of the interior towns of Cuba and in Orizaba and Linares, Mexico, and in Merida. At some interior towns, as at Jalapa and Guatemala, it has been reported absent after search.

To determine its distribution in the United States, correspondence was entered into with gentlemen in nearly every town on the Atlantic, Gulf, and Pacific coasts; as well as in nearly all towns of any size on the Great Lakes and on the Mississippi and Ohio rivers, and a considerable number of towns inland. In quite a number of instances, especially outside of the so-called yellow fever district, no sufficient search known to my correspondents had been made for this insect; but in the majority it was possible to obtain a satisfactory answer, negative or positive; and from quite a number specimens of Stegomyia fasciata were received.

To enumerate all the places at which it was found in the United States would take too long. Generally it is reported as found in all of the coast towns from Norfolk, Va., to Galveston, in which a sufficient search has been reported as made. It was also found at a number of interior towns: Houston, Texas; Shreveport; Franklin, and other towns in South West Louisiana; in Biloxi and Pass Christian and in some other places, in the interior, of Mississippi; in several towns—at all of which search was

*Read at the annual meeting of the American Public Health Association, Washington, D. C., 1903.

made—on the Mississippi River, up to and including Cairo, Ill.; also some interior, towns in Eastern Georgia. It is the less necessary to give the details of this distribution as I had intended doing, as I find Dr. Howard of the Department of Agriculture has also been engaged, with infinitely better facilities and success, in collecting data on the distribution of *Stegomyia fasciata*, and as soon as his report is published we will have complete data on the subject. He writes me: "The list of localities from which I have received it is a long one. In general, I may state that, in my opinion, this insect will be found practically in all portions of the lower austral life zone in the United States. This includes all of the Gulf States, as well as portions of New Mexico and Arizona; it also includes the low-lying portions of South Carolina and North Carolina, and the Southeastern portion of Virginia; it includes also Southern Arkansas and Southern Indian Territory, as well as Western Tennessee and Western Kentucky, the extreme southeastern corner of Missouri and the extreme southern tip of Illinois." Obviously, my district is included in his more complete life zone of this genus.

Within this district mosquitos of this form have been reported absent; that is, not found after sufficient search, at the Quarantine Stations at Ship Island, Mullet Key, Blackbeard Island, at the Savannah Quarantine Station; at the Cape Fear Station, and at the adjacent town of South Port, N. C.; nor have they been found on St. Catherine's Island, Ga. They have been found aboard in-coming vessels at all save one of these stations, but none have been found ashore. We may note that Ship Island has been notoriously "non-infectible territory"; at the others I know of fewer exposures. All of these stations are wind-swept, isolated places, with abundant marsh, fresh and brackish, in the vicinity, with artesian water at the first and last, and cisterns carefully screened at Mullet Key. I do not know the water supply at the Savannah Station. They were found at the Brunswick Station, but have disappeared under kerosening. Here cisterns were used.

The answers received from north of the Ohio and Potomac were decidedly less satisfactory than from points south; the Stegomyia having apparently excited little interest in the former, and hence not having been as carefully sought for. They are reported as absent, after careful search, at Evansville, Cincinnati, Baltimore (except a few larvæ which developed into Stegomyia found at the fruit wharf in early September), Lewes, Del., and the Quarantine Stations of Delaware Breakwater and Reedy Island. They were not found on Staten Island or Governors Island, or at the New York Quarantine Station, or at Buffalo, or Sault Ste. Marie. The writer especially regrets that he cannot say definitely whether they are found in Washington or Louisville, places which are on the border of their apparent range. He is sure that they are at least rare in both places, competent observers, although not especially on the search for this form, not having seen them. Indeed, considerable search has failed to show them at Louisville.

On the West coast they are reported absent at San Diego, and at Angel Island, San Francisco Harbor, and are not reported as present at any port.

In spite of those found about the fruit wharf in Baltimore, it seems that they practically do not occur north of Cape Henry, and that they are found at all of the cities south of Cape Henry at which satisfactory search was made. Thus the old line of division for Maritime Quarantine; a line founded empirically on the spread, in recent years, of yellow fever when introduced, "The Southern boundary of Maryland," was a fairly correct division of infectible and non-infectible territory. Indeed, the old rules of Maritime Quarantine for Southern ports are, except the disinfection of baggage, very generally applicable under the theory of its conveyance by this mosquito.

In America this form has so far been reported found only about the habitations of men (at least the writer has been able to find none elsewhere reported). This was to have been anticipated, because (1) the conditions which prevail about houses are especially suitable for its propagation. (2) Being easily found about houses in districts where it exists, it may not have been looked for elsewhere. Yet it is a matter of importance to determine if it breeds in woods, fields, or swamps distant from human habitations. In the United States the *indirect* evidence of yellow fever not spreading when introduced into new camps in the woods and fields—and cypress swamps as well—is against the natural occurrence of this form in such places in the United States.

If this be true of the tropics as well, Manson's proposition, to de-forest and drain a belt ½ mile wide on either side of the Isthmian Canal to prevent Stegomyia boarding vessels in transit, is unnecessary. It would be wiser to depopulate it.

Conveyance from Place to Place.—Obviously if they are conveyed from one place to another this second place becomes infectible, temporarily, in proportion to the number received; and if the Stegomyia breeds and thrives in its new home, a settlement, more or less permanent, is established; and places which hitherto have received yellow-fever patients with impunity can do so no longer, but become, as long as the Stegomyia prevails, infectible.

This change of infectibility not predicating the cause is fairly common in the history of towns in the interior of the Gulf and South Atlantic States, and not uncommon even in that of coast towns. Thus, Norfolk, Va., prior to 1855, had had yellow fever introduced a number of times, "almost every year," and occasionally there would be secondary cases around the wharves—there was then a large coffee trade. In 1855 there was a severe and general epidemic. Fernandina was the place of refuge in 1876 from the epidemics in Savannah and Brunswick. In 1877, following the advent of a vessel from Havana, a general epidemic arose; and again an epidemic in 1888. Jessup, Ga., gives a similar history.

(*a*) *Conveyance by Railroads.*—The writer has been able to find no conveyance of this mosquito by railroad, nor has he been able to have any sufficient search made for them aboard trains running from towns which harbor Stegomyia, except at Evansville, Ind., by Passed Assistant Surgeon Brown. He has then no *direct* evidence that they are thus transported. As other mosquitos, notoriously the culicids, are transported by trains, it is highly probable that they also are thus transported, and the cases of yellow fever contracted in St. Louis and Louisville, toward the close of the epidemic of 1878, by local railroad men and residents near the stations of railroads from the south is indirect evidence that is very convincing. To what extent this occurs should evidently affect our measures of inland quarantine.

(*b*) *Conveyance by Vessels.*—Conveyance by vessel has been frequently noted. It is fair to say that the Stegomyia not being found aboard a vessel is evidence of its absence, of value only in proportion to the process of search adopted and the care taken in making it; and it seems fair to say that they are conveyed by vessels in small number far oftener than the reports we have would lead us to believe. A negative statement of the crew is of little moment.

People used to the fiery bite and myriad numbers of the "salt water mosquito" (C. sollicitans), which infest the wharves of tropical ports, pay little attention to a moderate number of elusive Stegomyia. Probably the best way to determine their presence is to put out breeding cups or, which indeed is better, to look for such receptacles as may have served for this purpose aboard. Failing this there seems no better way than direct search. Corput of South Atlantic Quarantine Station says: "I personally search all corners, closets, hangings, and roofs of berths. A favorite place is in the corner over the shelf where the water bottle and glasses are kept; also the carpenter's shop on account of the water under the grindstone." In cargo vessels where the cargo is a food for mosquitos, such as bananas, sugar, etc., they would most probably be found in the hold. There would almost certainly be water enough for their drinking in the hold, if only from condensation on the sides of the vessel, if an iron vessel. It is of course in vain to look for a small number of mosquitos in the hold of a vessel, except by breeding cans.

Although conveyance by vessel has been frequently noted, yet they have been found aboard but a small proportion of vessels examined. Souchon's inspectors, in 1892, found Stegomyia on only two fruit vessels in New Orleans out of a considerable number examined; the mosquitos of this variety constituting 2½ per cent. of the mosquitos found, while in the houses at the port of departure they were 40 per cent. of captures, this disproportion is in accordance with what we shall learn of their habits.

They have been found at Ship Island Quarantine aboard three vessels sailing from Vera Cruz. A considerable number of vessels were examined negatively. At Tampa Bay Quarantine Station, aboard one vessel sailing from Buenos Ayres. They had bred aboard in the water tanks, as had those in one of the previous cases. At the Savannah Quarantine they were found aboard two vessels, from Cape Town (direct) and Havana respectively, both sailing vessels, and aboard both "water barrels were alive with wrigglers" which developed into Stegomyia. At South Atlantic Quarantine aboard five vessels, three sail, two steam; from Rio, Buenos Ayres, Lorenzo Marquez and West Indian ports. At Brunswick Quarantine Station aboard three sailing vessels, all from Havana. Larvæ were abundant aboard these three, and aboard four of the five at South Atlantic. Nothing is said of larvæ aboard the fifth, a steamship.

Goldberger, at Tampico, found them aboard three steamers, on arrival from Vera Cruz. None on a considerable number from New York.

The writer has found Stegomyia at Baltimore aboard two fruit steamers, from Jamaica and East Cuban ports, and, as noted, has bred a few of them from larvæ taken from near the fruit wharf, while nowhere else in Baltimore has he been able to find them.

The "Working Party" (Parker, Pothier, and Beyer), from observations at Vera Cruz, believe the transfer by iron vessels is rare, while by sailing vessels it is far more common. They base their opinion upon the paucity of suitable breeding places on the iron (steam) vessels as compared with the wooden (sailing) craft. "The iron ship, on account of its concealed water tanks, acts simply as a mechanical host to those that come aboard, while aboard wooden vessels, on account of the loosely covered deck containers, under proper conditions they propagate." While their observations are not sufficiently numerous to warrant the general deduction that iron (steam) vessels rarely carry this mosquito, yet their estimate of the comparative frequency with which steam and sail vessels convey *numbers* of them is undoubtedly correct. It is in accordance with the few observations given above, and also with the indirect evidence (as has been frequently pointed out by the writer), that yellow fever is contracted aboard sailing far more commonly than aboard steam vessels.

There can be no doubt then, but that these mosquitos are carried from place to place by vessels, especially sailing vessels, for indefinite distances (Cape Town to Savannah) in tropical waters. This is of interest on two accounts:

(1) It is a means of conveying the infection of yellow fever to other countries: (*a*) by mosquitos coming aboard already infected, (*b*) by mosquitos becoming infected after coming aboard by feeding on cases of yellow fever developed aboard, but contracted ashore. Of course if there be no Stegomyia aboard, the occurrence of yellow fever among her personnel will not "infect" the vessel. In the absence of the host yellow fever is not a communicable disease.

(2) The conveyance of uninfected Stegomyia to a country hitherto free from them, where they will propagate is, also a thing to be deprecated, as it renders the country in question "'infectible" if cases of yellow fever be subsequently introduced. Conveyance to a place where they will not increase is of little or no importance.

There is evidence, and it is, I think, generally held, that this mosquito is not indigenous to the United States, but was thus introduced from the tropics, and has from this become a permanent inhabitant of the Southern Atlantic Coast and Coast Plain, and the Mississippi Valley North to Cairo, Ill. The writer also holds this as an opinion, but he does not consider it proven for the southern part of this area. I think, however, that it is unquestionably true that Stegomyia was thus introduced into the Hawaiian Islands, where it is now abundant and widely distributed, these islands being free from mosquitos until 1826, when they were introduced by a vessel from San Blas, Mexico.

We have said that the introduction of the uninfected Stegomyia into an environment where it did not increase was of no moment. This is true, but there is another question. Is this form able so to adapt itself to a somewhat unfavorable environment that it can become, so to speak, acclimated? Can it, after some generations, thrive and increase normally in environments in which at first it could do so poorly, or not at all? Can it by a series of generations in environments increasingly unfavorable—all being unfavorable in the same way—finally propagate and thrive in a place where the parent brood would have died without successors? This is certainly true of other forms of animal life, generally in proportion to height in the scale of life. It was, and I believe is still, held true for the "Texas tick," also the host of a pathogenic parasite, and certainly has some antecedent probability. The Vera Cruz working party believe this to be true and give reasons for their belief; yet to the writer they seem probable rather than conclusive, and he can only say that further observation is needed to answer the question, and that to answer it merits further observation. It is also conceivable that conditions, climatic and otherwise, may suffice for the host to thrive and yet not be such as to suit its parasite, and thus the temperature limits of yellow fever and the Stegomyia not be identical. This, that the host may thrive under conditions incompatible with the life

or development of the parasite, is alleged of the Anopheles and the Plasmodium Malariæ, although I think, not generally accepted.

Method of Propagation.—(*a*) All observers note that by preference this form elects to breed in clear water, not necessarily clean water (Reed added small amounts of fecal matter to his breeding jars) in artificial containers, cisterns, tubs, barrels; cans, etc. Theobald classes them as "almost exclusively a can and pot-breeder."

The New Orleans Mosquito Commission of 1902, in the part of the city where the above class of receptacles were available, found Stegomyia larvæ in 60 per cent. of them, and in only 10 per cent. of gutters. On the outskirts of the city where such receptacles were not available the same commission found them in nearly 80 per cent. of the gutters examined. Other observers, however, have found them far less frequently in gutters and pools even when there were no other breeding places. The "Working Party" in Vera Cruz found Stegomyia larvæ seldom in gutters, almost invariably in water cans. Taylor of Las Animas Hospital, Havana, after finding them commonly in artificial containers, notes that they "are also found in pools," as if it were rare, and this is the general testimony of my correspondents who have found them breeding in the United States.

Muddying and disturbing the water in the pool causes the death of many of the larvæ. Possibly on this account the pools on the outskirts of New Orleans were more suitable for breeding than those in the more inhabited parts of the city, indeed a still, undisturbed pool of water, cleared by standing, should, for this purpose, differ in no wise from a hard walled receptacle. Stegomyia is not a cesspool-breeder.

(*b*) The time from egg to fly is from two to four days shorter than others of its general order, Culicidiæ.

(*c*) Eggs are at times laid above water, and if kept dry, will preserve their vitality a long time. Finlay has kept eggs dry six weeks, Theobald, eggs received from Finlay, over two and a half months. and Reed ninety days, and then hatched them, The latter states that freezing does not destroy their fertility.

Its choice of breeding places indicates the especial danger of open cisterns; water-jars and collections of water in any artificial container; cans, troughs, etc. Thus the measures for their destruction are in contrast with those against Anopheles. In Gorgas' work in Havana the "Stegomyia Brigade" waged especial war in town, and on artificial receptacles about houses. The "Anopheles Brigade" drained and kerosened puddles and pools in the suburbs.

It is well to note that the larvæ are not gotten rid of by emptying the water-jars, as is usually done in daily use. The "Working Party" in Vera Cruz found that when water was poured from a jar the larvæ present sought the very bottom and, unless the jars were tipped up so as to empty them completely, which was not usually done, nearly all the larvæ remained in the jar.

Obviously then the introduction of water by pipes into a l hou es, rendering the keeping of water in containers unnecessary, is a most important measure in freeing a town of this mosquito. Natural pools, however, must by no means be neglected and the advantage of drainage, and with drain underground in place of open gutters, is especially from the observations in New Orleans, equally obvious.

The slightly shortened period in the egg and larval state, and that the eggs are occasionally laid above water and may preserve their vitality almost indefinitely, plainly add to the preservation of the insect and this latter may be a means by which it survives the winter in (for it) north latitudes.

(4) The Habits of the Adult, Female:

In spite of some statements to the contrary, the evidence seems conclusive that only the female Stegomyia feeds on man, or if the male does so, it is extremely rare.

(*a*) She is very long-lived. Theobald has kept them alive two months from the larvæ without food; these specimens finally dying for want of water. Of eleven mosquitos, five days old, fed by Guiteras on a case of yellow fever and hence infected insects, only two had died on the forty-first day, five lived over 101 days and one 154 days.

(*b*) Having acquired the power of communicating yellow fever they preserve it apparently as long as they live. Reed reports yellow fever transmitted on the fifty-ninth day after feeding on a yellow-fever patient.

The conveyance by vessels shown before, together with the long ife and persistence of this mosquito in transmitting yellow fever increases the difficulty in protecting the countries of the Old World, where the Stegomyia fasciata is found, from yellow fever. Because although so distant that it is not possible for a man contracting the disease in America to contaminate mosquitos in, say Japan, yet it is perfectly possible for a mosquito contaminated in America to infect a man in Japan, and from him a number of Stegomyiæ.

Hitherto there has been but little direct communication from the yellow fever ports on the West coast of America with the East (all the coast of America from Payta south and from Cape St. Lucas north is free from infection); but this may not be the case when the inter-oceanic canal is open. Yellow fever introduced into a country like India or the Straits Settlements might well become endemic and if so, such countries would in turn be a continual menace to the rest of the (infectible) world, repeating the history of Rio Janeiro and, probably, that of Havana.

(*c*) They are essentially house mosquitos. Not only do they breed best under the conditions which obtain in and about houses, but having entered a living house, they do not like to leave the premises. Here again their habit is in contrast with that of Anopheles. It was the almost universal existence of this mosquito in the houses of Havana which first led Finlay to select it as the probable conveyor of yellow fever, an essentially house disease. Indeed his early arguments based on the phenomena of yellow fever and the peculiarities of this insect dovetailing in with the theory of its conveyance of yellow fever to man is an extremely beautiful piece of deductive reasoning.

The limitation of infection to the neighborhood of houses which contain or have contained yellow-fever patients is a marked feature in the early part of an epidemic.

(*d*) It requires a considerable interval of time, generally about fourteen days in summer, after feeding on one sick of yellow fever before the mosquito is capable of imparting the disease.

If then the mosquitos be destroyed or all persons be removed soon after the first case of yellow fever develops in a place, no one will have been exposed to infection and these people need not be regarded as suspects. The minimum limit of this "extrinsic incubation" of yellow fever is not certainly fixed. Twelve days is the shortest which has been so far found in experimental cases.

(*e*) *Its Time of Feeding.*—Observers seem to

gree as to its hours of feeding, but the disagreement s more apparent than real. All agree that its prinipal time of flight is in the afternoon: It is "essenially crepuscular." Reed says: "after four o'clock. he New Orleans Commissioner: "especially in the fternoon hours." The Vera Cruz Working Party tates "early in the morning and late in the afternoon. t does not feed in the dark nor does it in a strong ght, and its feeding seems more dependent on the egree of light than on the time of day. If the place e fairly light it approaches its victim on the shadow de, thus especially attacking the ankles under a riting table, or the hand under the head during esta. It bites after dark if there be artificial light the room. It does not bite out of doors in ordiary bright daylight.

The above habits, together with the fact of its ing a house mosquito and the infected insects ing mainly confined to dwelling houses, explain e comparative safety of "day-light communicaon," *i.e.* entering a town only after 10 A.M. and aving by 4 P.M. under pledge to go in only on nny days and to enter no residence; sometimes t to go into the residence portion of the city. The nger of staying all night was really the danger of late afternoon, early evening, and morning urs spent, of course, in residences.

(f) *Hybernation.*—Many species of mosquito are own to hybernate, some as adults, some as wrigrs, and some doubtless as both. L. O. Howard, quoted by John W. Ross, states: "That the egomyia hibernates in the adult stage." I have t seen reported the instances on which this statent is based. Guiteras placed thirty-three mositos in an ice-box at 46.5° to 50° F., without d or water; three of them survived to the hty-seventh day, when they were eaten by ants. That the species habitually hibernates, *i.e.* ists quiescent through the winter, either as adult, va, or egg, is beyond dispute. Admitting that y hibernate as adults, our experience with yellow er teaches us that either but a small proportion *infected* insects survive, as indeed the experience Guiteras would indicate; or else that the power convey yellow fever is generally lost after hiberion. For while there is much evidence, and it s generally been accepted, that yellow fever asionally recrudesces after a winter of quiesce without re-introduction, yet it is certain that is not the rule. In a large majority of places ere this species unquestionably hibernates, reudescence of yellow fever after an epidemic has t occurred, and, even when it is claimed to have curred, only a small proportion of the infection at existed when the epidemic ceased is observed the beginning of the recrudescence. Unquesnably then, Stegomyiæ capable of conveying fection at the beginning of cold weather are only ceptionally—and very exceptionally—capable of aveying it after a winter in the Gulf States. Of urse it may be that the parasite dies in the hiernating host which survives.

(g) *Aërial Conveyance.*—Some mosquitos are carl occasionally great distances by the wind. The iter has personal knowledge of the flights of yriads of mosquitos (Culex solicitans as he remembers) which were carried by wind fifteen or ghteen miles from the Louisiana marshes across andeleur Sound to vessels in the sound and to andeleur Island. In both cases the wind had own moderately and steadily for two or three ys from the marshes. Other instances are reorted; and, in spite of the general opinion of men r abler to express an opinion on the subject, the riter thinks from his observation afloat on salt water in the lee of islands and mosquito-infected shores that the Culex of the salt marshes is quite frequently carried considerably over a mile by light, steady breezes, long continued.

Is this true of the Stegomyia? It is a far lighter insect, more fragile and apparently with very little wing power. It probably never flies high. It is found, by preference, in the lower stories of houses, and would thus be little liable to conveyance by wind, and its feeble power of flight should prevent its passing over any considerable distance by its own wing power. Nearly two years ago, the writer suggested that this problem be taken up, it being of importance in determining the anchorage of vessels in yellow-fever ports. So far he knows of no direct observations on this subject, except those of Goldberger at Tampico, and of Grubbs at Ship Island Quarantine. The latter found Stegomyiæ aboard three vessels from Vera Cruz, two of which claimed to have lain a half mile from shore. He believed they came aboard at Vera Cruz. The observation of Goldberger will be given later.

Although direct observations on this problem are few, yet there are certain indirect ones, bearing, however, entirely on the aërial conveyance of the Stegomyia infected with yellow fever. It is notorious that yellow fever is usually conveyed but a short ways aërially, "across the street," or, more often "to the house in the rear," which is about as far as it was expected to be thus conveyed. This represents a maximum distance of about 75 yards. The two longest distances recorded in recent times of aërial conveyance, one of 225 meters (Mèlier) and one of 76 fathoms—456 feet (the writer) are entirely exceptional. So much for the distance which the (infected) Stegomyia is conveyed—or rather usually conveyed—aërially.

On the other hand it is known that vessels moored in certain districts of the Havana harbor did not develop yellow fever aboard, except in those who had been ashore, or unless they lay close to other vessels which were infected. This experiment has been made on so large a scale—with so many vessels and for so many years—that we must accept as a fact that an infected Stegomyia was not conveyed aërially from the Havana shore to those vessels, or, allowing for errors, was very rarely so conveyed. The distance which had been found safe was something over 200 fathoms—1,200 feet. The prevailing wind was generally slightly on shore, but was not constantly blowing. Whether there is any difference in the distance to which infected or non-infected mosquitos are conveyed, is, of course, entirely a matter of surmise. There is no apparent reason why there should be. Yet the infected Stegomyiæ have almost certainly become so in a house; and with their very domestic habits must be found out of doors, where they would be subject to conveyance by the wind, in much smaller numbers than the uninfected insects, and consequently a lesser *number* of them would be conveyed aërially. Observation is needed on this subject—the distance (across water) that Stegomyiæ are aërially conveyed.

Goldberger, very ingeniously, suggests that on account of its diurnal flight, the direction of the wind during the day only need be considered in estimating this factor in their aërial conveyance, and states that at Tampico he has failed to find Stegomyiæ aboard vessels lying, for ten or fifteen days, about half a mile from a shore where they were abundant, while numbers of Anopheles albipes and Culex pungens were found. The wind was on shore during the day and calm or off shore during the night. The importance of this point is obvious, as

on the coast, except when overborne by the trades, the direction of the wind is very generally different by day and night.

To sum up:

Among the special characteristics of the Stegomyia which affect its rôle as a carrier of yellow fever are:

1. *Its distribution.*—This is generaly between Lats. 43 N. and 43 S. on the coasts and low plains of Africa, Asia, and the adjacent islands; Australia and the Mediterranean basin of Europe. It is also general on the eastern coast of America from 38 N. to 35 S. Lat. On the west coast it is found at Panama and Guayaquil, and its existence is *implied* from Guayaquil to Acapulco. In the United States it is general on the coast and low plains of the Southern States, except Maryland.

2. It is conveyed by vessels indefinite distances (from Cape Town to Savannah Quarantine); in much greater numbers and more often by sail than by steam vessels.

3. It lives a long time—154 days being recorded of an infected insect. Once having acquired the power of transmitting yellow fever, it retains it apparently as long as it lives—59 days being recorded. A consideration of the three postulates above will render it advisable to safeguard the tropical countries of the East when communication is opened up betweeen them and American ports infected with yellow fever, preferably by freeing the American ports of yellow fever.

4. It propagates preferably in artificial containers, but will propagate in pools where such containers are not available.

5. In America it has been reported only in the vicinity of human dwellings, and seems here not to be a sylvan, paludal, or campestral mosquito. From 4 and 5 the war against this insect in America should be waged about the houses of men, and especially against water in artificial containers. The introduction of a water supply, piped to every house so as to do away with cisterns and water-jars, is the most important measure of sanitary engineering to free a town of this mosquito. Next to this is a system of drainage by covered drains to carry off the rain water and prevent pools. Cesspools are not objectionable on this score.

6. It unquestionably hibernates in the United States, but if the infected adult hibernates, either a very large proportion of them die, or else the infecting parasite must *generally* die in the hibernating mosquito. The first seems more probable.

7. It is essentially a house mosquito, and is inclined to stay about the premises where it has fed. Hence the greater safety of the whole district of an infected city as compared with the residence portion.

8. It does not feed in the dark or in bright sunlight. Therefore, in bright daylight or at night without artificial light are the safest times to be in an infected place.

9. The cycle of the yellow-fever parasite in the mosquito before it can be conveyed to man is generally, in hot weather, about fourteen days or over. Prior to the accomplishment of this cycle (once called the "extrinsic incubation of yellow fever" the mosquito cannot convey this disease.

10. It is probably usually conveyed aërially less than 100 yards. In Havana the infected insect is believed to be never aërially conveyed 200 fathoms—1,200 feet—from Havana shore. The direction of the prevailing wind during the day influences its aërial conveyance.

THE UNCLASSIFIED TROUBLES OF WOMEN.

By EUGENE COLEMAN SAVIDGE, M.D.,
NEW YORK.

The advantages of classification are obvious, for classification is indispensable. Psychologically, man is a classifying machine. The disadvantages are only apparent as we advance in experience and find so many borderline examples, overlapping several classifications.

It is to this borderline region that I call your attention, and maintain that certain troubles not sharply defined as gynecological, are really the most important and productive in the specialty; that these troubles are neglected by our leaders, judging by what they write upon and discuss; that the general practitioner, without genecological training, cannot grasp them thoroughly; and that the profession, and back of the profession, the community, are dependent upon us as specialists to study and solve these problems.

First, a brief personal note. Man, in so far as he is an individuality, is a selective principle. We can no more explain this subtle individual quality than we can tell the selective secret of digitalis for the heart or strychnine for the spinal cord. The spirit of a given mass of facts will be refracted differently through the prism of different individualities. My modest conclusions are the result of this selective principle acting upon the material that fortune has thrown under my observation. I give them as supplementing the work of others—not opposing, as some of my confrères have thought. But there is vigorous opposition in my standpoint to the narrow-constructionists—if there be such—who would hold that gynecology is not a science of all the troubles of women, but a branch of surgery restricted to the uterus and its appendages. Such a view would make us simple abdominal or plastic surgeons; whereas the very brilliancy of this big, objective, macroscopic work has established a new branch of medicine and has accordingly brought upon us the responsibility for much that is more obscure, yet as important as the definite work forming the substance of our textbooks. This unclassified work as yet has not been thoroughly exploited and mastered. The principal fact with regard to a woman is her sex, and all that arises from this urgent fact calls upon the responsibility of the gynecologist of the broader conception—whether it be hygiene, physiology, pathology, longevity, or even psychology—for woman has an extremely specialized psychology.

Speaking generally, there are certain important matters connected with that I have called "the feminine element," which make for a woman's longevity, and determine her resistance to many of the inevitables involved by her sex. Though these overlap the borderline of internal medicine, I insist strongly that they are gynecological. They are due to the entailment of sex; they most frequently focus symptoms upon the local organs; and we will fail most signally with them as mere localists.

Before coming strictly to gynecological matters, consider a few general propositions: How much can we do for a dilated heart; for chronic Bright's disease? Who can restore the obliterated calibre of the surface capillaries? We can palliate; we can not cure. And in the acute diseases, is not the breakdown almost always in the vasomotor system, the great tubular works of the body? Pass on pneumonia, on typhoid fever, on peritonitis, meningitis, the ruptured cerebral artery, the sudden heart failure at the top of the stairs where there have been no pain, no murmur, no suspicion to the mere localist—and one can be a "mere localist" at the heart as well

as at the uterine end. One man lives through his pneumonia; another's heart fails. One woman conquers her streptococcus infection; another's heart fails. Who can tell whether it is the integrity of the tubular system, the resistant power, or the strength of the infection; the reason may be all or one of the three. Is the resistant power of the clinched fist, the contracted body of the falling balloonist, greater than the same fist or body in unsuspected relaxation? We almost poison with strychnine in streptococcus infection to enhance vitality, as we say; but do we not rather clinch with our drug the entire fist of the tubular system. Who can say how much is physical condition; how much is dynamic addition? It is the same throughout the entire list of the acute troubles.

Now, if we can reach that heart before it dilates; arrest that Bright's disease before it arrives; force out the blood-vessel rust, so to speak, from the calibre of those surface blood-vessels before entire obliteration of the lumen—if we can underwrite these great tubular works of the body, which wear out in our American civilization long before the rest of the body, and keep them as young as brain and brawn—we can do far more than help our patients through their acute troubles; we can add an effective decade to the life of our adult population. We can postpone the class of hemiplegics, the spastics, the dotards, the superannuated, the back-numbers, to ten years later in life.

Gentlemen of the New York Obstetrical Society, I believe in the heartiest sincerity, that this can be done. Medical men, worn to the limit of their vitality in combating the classified diseases, have given little attention to the unclassified. At every opportunity I shall urge my conviction on this point. Could I accent it to the professional mind, like fire in the night, I would gladly limit my professional contribution thereto, and consider it ample. Once surveying this field, we have imposed upon us, in the language of Professor W. H. Thomson, "a special responsibility; for what ought we to try more to do than to save a fellow creature from awakening some morning with the terrible calamity of a hemiplegia, when it would have been better for many such patients afterward had that night's sleep been their last."

Now, why such a subject in a gynecological paper especially? For the best of reasons. Women are the transmitters of the race; men merely modify. Women suffer more than men in the tubular area, excepting the brain. The tubular conditions are directly hereditary. And women are the hygienists of the race in its infancy; they engrave the habits on the plastic mind. As a man's mother is, so is he. Gynecologists, therefore, must do most of this work if it is to be done.

What sadder picture of professional limitations can be presented than that of a patient in whom the great vasomotor changes have had their obscure beginning—who has her back-ache, her side-ache, her reflex neuroses—who is led to believe that the little cicatricial plug in her cervix uteri is the sum and substance of her trouble? (I am not underrating its importance when it is the sole trouble.) Or again, how terribly futile is the assurance that there is no albumin in the urine, or that there is no murmur in the heart—that "the heart's all right"—that there is "nothing in the parametrium"—when the then present moment is the time, and the only time, for the cure of the foreshadowed Bright's, the coming heart failure, or the pelvic thickening five or ten years off.

Becoming more specifically gynecological, let us consider some facts bearing more closely on the specialty. Consider them with an eye to the relation of gland function to elimination, circulation, arterial integrity, effective longevity.

Grouping the significances, I call your attention to the subtle differences between a stallion and a spayed animal; to the difference between a woman with ovaries and one without ovaries; to the practice of altering hogs to fatten them for market; to the combination of sterility and fat in the hairless man with tenor voice; to the relation of fat to the heart, the circulation, and elimination; to the frequently met condition of what I have called "the self-obliterated feminine element." This last covers two conditions in two different periods of life. In young girlhood, over-expenditure of vitality in intellectual or emotional pursuits will rob the organs and glands—the mammary, ovarian and perhaps thyroid—of their share, and thus leave them disqualified for their function of selecting from the general protoplastic mass that subtle something that constitutes the essence of femininity. This is by no means fanciful; a minor thing; a "cosmetic" question. It is as fundamental and important as the reason why a woman menstruates and a man shaves. It leads directly, as I shall elaborate, to a shortened life when life is most valuable.

The other condition of the "self-obliterated feminine element" is in women from twenty-five to forty, whose increasing lithæmia, growing obesity, conscious hebetude, diminished menstruation, and perhaps slight skin and voice roughening, and the development of a hairy tendency, show a strangling out in function of these important selective principles, which can be aroused from slumber and put to work with almost spectacular effect.

A treatise could be devoted to each of these conditions. This is gynecology in its double distillation; and the profession must reach to us for light on the subject.

There are even more significances belonging to this group, despite my long interpolation. I frequently invite the scrutiny of trained observers to the women in a mixed group of well-to-do persons. Take a Metropolitan Opera House audience on a star night, and scan the couples in the decade of adult summit. Look at the men—agile, keen, quick of movement, still in the game of life, of use to their family, age, and race. Turn to their consorts—save a few exceptions for our chivalry, they are obese or scrawny, hebetudinous or jerking, flabby bundles of tissue hanging in folds; each fold, to the esoteric eye, full of burnt-out tissue juice, poisoning the individual with the ashes of her own life. The difference is a sex difference, though not a sexual difference. It is due to the habits, ideals, environment, and especially the traditions of the sex. And, as such, it is a gynecological problem, the nature of which is not changed even by the conceded greater longevity in the female. There is a distinction between longevity and effective longevity.

Still following up this long line of significances: Take the relation of infantile uterus with Graves disease, leucocythæmia, pernicious anæmia and chlorosis—or with that indefined condition, conceivably pathological, which may be called a "general lusterless hebetudinosity." This muddy, bacon-like condition in a young female obviously modifies her conjugal destiny; I have elsewhere tried to point out the stages by which this condition reaches the operating table; and I earnestly believe that it gives us a notable opportunity to bestow years upon these patients—as definitely and calculably as though we had these years in our safes as entities and were handing them out. Who must work out these prob-

lems? The general practitioner, if he have opportunity and inclination, is qualified to become a gynecologist; but it is only as medical-gynecologist, and not as general practitioner, that he will get the grasp.

Take the relation between pelvic congestion in the female and renal insufficiency. We have theories but no real knowledge why a pregnancy, with its resulting congestion, throws out into prominence an unsuspected renal trouble, or creates a renal trouble: which is it? The obstetrician helps and even cures the renal trouble by emptying the womb—by mechanically relieving the congestion. Thus puerperal eclampsia, or distinct albuminuria, puts up a head big enough to see. But does pelvic congestion result only from pregnancy? And must we have death-dealing eclampsia as a menace before we get to work? Varicose ulcers on the leg, for example, tell how destructive venous congestion can be. And does venous stasis only work injury in the legs and leave the pelvis free? Is it not true that there are numerous causes for pelvic and abdominal congestion in the female; that they have marked bearing upon the organs of elimination even when reaching no inflammatory condition; that they are relatively more important than eclampsia, because insidious and hidden—occurring in thousand to one frequency—and underlying the dreaded general arterial sclerosis; that they belong to gynecology though their results classify them with general medicine; and that these unclassified troubles, none of which rises to the dignity of a disease, are often unseen by patients and their advisers until they grow formidable enough to come under a classification?

Take the important but delicate question of maladjusted sexual relations, with its physical, psychical and sociological aspects. This is a good subject for a valedictory paper if a man would utter his conviction. To quote the *Sun*, "To the pure all things are *im*pure." I personally prefer not to waste the energy of an acquaintance on those "nice persons with nasty minds" who are always "wondering what one means" by almost any simple declarative sentence. Psychologists well understand the essential uncleanness of prudery. Nevertheless, a rich group of unclassified troubles under this head demands the bravest and most thorough work—a work that only a gynecologist can do. These troubles are *functional* merely, as we sometimes lightly say; there may be little that is objective about them. But do we sufficiently realize the gravity of "merely functional" matters? A death-dealing heart-failure is "merely functional"—that is, the difference between the heart that stopped and the heart that went on, is too subtle for material analysis, and we hide behind the term "vitality." I have many details under this heading, which despite brave speech I prefer to withhold for later papers. Much of this "merely functional" disorder reacts on the eliminative and circulatory machinery, and so eventually comes under the life-robbing head.

Then take the menopause. This is well classified as a fact in gynecology, but unclassified as to detail. If the profession agrees with me here, I bespeak its authority for my postulate on this point. Bear a moment with my example, for I consider that a secret lies here that holds years of useful life to woman. We must restrict our consideration to those of higher evolved nervous structure. Unfortunately for the democratic formula, there are decided class distinctions in medicine, and particularly in our specialty. You cannot apply a stolid German theory to a volatile French subject. The deductions from a thousand European peasants might fall short in the case of one highly strung American woman of expanded psychology. This explains why Christian Science, for example, is an American plant, and does not flourish among those of lowly nerve structure. I believe that the secret lying underneath this Christian Science movement can be applied by us here: I mean the power for healing and life in the human mind. Let me not be misunderstood. I believe that this wretched error of Christian Science—which has turned over millions of money and put new architecture in the landscape—has in it a very potent germ of truth, an underlying secret, which we medical men have neglected and should more largely apply. There is an appreciable power for life and healing in the human mind, which I have elsewhere tried to show can almost be computed in material terms—that power which enables the men of brain to outlive the men of brawn in the shipwrecks, disasters, Arctic expeditions in history. And nowhere can this be so beautifully demonstrated as at the menopause. (And I remark parenthetically that Christian Science is principally the cult of those past the menopause.)

We know so well the objective, physical picture of the woman after the menopause—the intestinal fermentation, the hardening arteries, the facial eruptions, the red nose, the herpetic and adhesive vaginitis; the changed shape of the vagina—from triangle with apex down in youth, through the parallelogram form to triangle with apex up in age, so that you cannot tampon readily. This change in the shape of the vagina will typify the change in the general outward shape of the body, which I call—with no disrespect to royalty, but that all may know it—the Queen Victoria figure, a triangle with base below, running to the apex at the head.

This is the physical picture; but what of the psychology of the woman between forty and fifty who finds her menstruation coming irregularly for the first time? It is not necessarily the gray hair, the wrinkle, the eye-glass, the apex of a vagina, or the Queen Victoria figure; for these may reach one without this psychological involvement, years sooner, as in the case of the "self-obliterated feminine element." It is not that the woman loves the monthly infliction, nor that she wants more children—what then is the climacteric anguish?

I believe it to be a psychological matter which aggravates enormously the physical condition. The woman's children are grown and married; her activities have dwindled; she is in the position of a man retired from business. And then, foremost in insistence, is the tradition that tells her she is through with sexual life. And just as male alcoholic paresis gives as an early symptom an unreasoning jealousy of the wife, so in the female at the menopause we have an analogous psychical symptom, often aided by the temporary lull in male sexual power around fifty, when the prostate begins to thicken. Brought to naked daylight statement, the woman's unformulated psychology is that she is through with sexual life, its joys; and, principally, that she is passing from her utility to her husband and her family. And this bows her head to the expected sword. She spends her time waiting for the end in manufacturing lithæmic products. So we have focused on a single point influences that conspire to rob the woman of what should be the best years of her life.

I must again sharply emphasize that I am speaking of women of a certain grade. I must again distinctly state my conviction that there is scant democracy in physical life: much in anatomy; some in physiology; almost none in psychology, which last is the important point. To the brain livers only does this best period of life prove a best period when the psychical joys are appreciated and are as much greater than joys of sensation as the mind is greater than the body. Here Christian Science has stolen

r opportunity; it has few devotees in the tene-nts.

I doubt the kindness in the attempt to add to the bmerged ten years beyond the time of physical ac-vity. With no mental life; with no financial re-urce; with the almshouse, or dependence on those ready engrossed with the care of a new generation, almost seems kinder to view life with them bio-gically.

But with the others it is vastly different. And re we may apply gynecology, and some sociology, its highest form. I want to build some more fire the night on this point. I want to bespeak the gma of the profession that in these foreseeing ovident walks of life, with those who have a house the mind in which to dwell, the menopause is only second commencement—a new graduation day—a woman's life. The child-bearing period, like the hool-day period, is a step toward the period of ult summit, of which the menopause is the thresh-, where should be found the best years of life. st the uncertainties of youth, with its burning pas-ns; past the self-sacrifices of child-bearing; rough the shifting process by which the fittest rvive; in possession of the proceeds of the last neration—the life of greatest utility to the family d community should begin.

We can keep our patients at the menopause from coming uric-acid machines; we can keep their arter-soft; we can abolish the Queen Victoria figure, red nosewings, the boborygmus, the toxic head-hes, and the loose flesh folds which are simply man sewers. And we can thereby add ten years useful life.

The object of my paper is not to show how to do tain work, but to point out certain work to do. has passed beyond the theorizing stage with me; is my daily routine; and so high a mission do I nsider the field that I should personally gladly render the classified field for the unclassified. I ak therefore whereof I know when I call it one of most valuable branches of gynecology. I be-ve that some life is more valuable than some other . Life has an actual and a prospective value. e actual value of an effective life at adult summit greater than that of a hundred infants in a ma-nity hospital. The prospective value of infant life only realized as it joins this actual value group. en the sentiment brought by the child to the rent is a force finding its value in the adult period. course our present subject does not consider the pulating of a predicated heaven with fetal and antile souls.)

If the profession can add an effective decade of the t kind of life to a portion of our eighty millions, Colonel Sellers we can figure the year-value derlying work in the unclassified field.

These troubles are not revenue-producing from a cialist's point of view; they yield no large oper-ng fee; no medical man will send us such patients whom they feel qualified to do as well; and work ng these lines is only possible to those with a per-al following. Nor even will the patients ever know m what we have saved them. But we will know d our intelligent confrères will know; and this is not only point in the profession where our reward is psychical as some of our therapeutics should some-es be, and are not.

Women have lacerations, retained secundines, pus bes, ectopics, fibroids, and cancers. And we oper-e on them brilliantly, with this or that technique, whose minor details we spend much time in dis-ssion. But in all these things—I am not sure that will except even the malignant troubles—we get hind the outward symptom and arrive at first causes when we "get them together" in the tubular system, as we clinch our fist, or contract our body when expecting a blow. We thus symbolize the great passion of the universe—the movement from circumference to center—"the love of a ton of lead for the center of the earth."

Because unclassified these troubles are not "distinctly defined forms"; and because not "distinctly defined forms" they seem non-existent to those without synthetical habit. I respectfully submit this attempt to make them a distinct and manageable entity for discussion and debate.

66 West Fiftieth Street.

A DIAGNOSTIC SYNDROME FOR INTRACRANIAL SYPHILIS. WITH REMARKS UPON PROGNOSIS AND TREATMENT.*

By WM. BROADDUS PRITCHARD.

NEW YORK.

ADJUNCT PROFESSOR OF MENTAL AND NERVOUS DISEASES, NEW YORK POLYCLINIC; CONSULTING NEUROLOGIST, S. R. SMITH INFIRMARY, STATEN ISLAND.

If there is any one disease possessing an interest and importance common to all physicians in every branch of medicine, that disease is syphilis. More than any other, it constitutes a centralizing factor and stands for a community of interest in the profession. In nervous and mental diseases syphilis is of pre-eminent interest. Indeed, so common is it and of such relative importance as an etiological factor in affections of the brain and spinal cord, as almost to justify a pharaphrasing of the Latin dictum: That man is a neurologist who knows *everything* about syphilis, and *something* about neurology. It is beyond question, the most prolific single cause of disease of the cerebrospinal tissues. In my own experience, covering a period of some sixteen years of special work, it enters as a factor, singly or in a dominant contributory way, into the histories of more than 40 per cent. of all my organic cases. I am not so sure of my figures as to its frequency in mental affections, but it is certainly and admittedly common and with equal certainty quite important. Strictly speaking, it is a paradox to describe syphilis as ever a cause of the neuroses, in that syphilis practically never induces any persistent nervous symptoms except through the medium of some underlying structural changes. As a cause of the pseudo-neuroses, however, its manifestations are legion. Perhaps the most remarkable and interesting attribute of syphilis in neurology is its infinite capacity for simulation. Someone has aptly termed hysteria the mockingbird of disease; to an even more striking degree would this simile apply to syphilis. So varied and widespread are its clinical manifestations and mimicries as to leave outside of its sphere of vicious activity scarcely more than a dozen of the many hundreds of types and subtypes recognized in neurology. Meningitis, encephalitis, myelitis, tumor, thrombosis, hemorrhage, aneurysm, obstructive endarteritis, tabes, and epilepsy are familiar types often due to this specific cause. It is the basis of many of the scleroses. Among mental diseases I have seen occasionally a symptomatic melancholia or mania yield to the iodides or mercury, while paretic dementia is a type well-known as standing in a sequential relationship to this cause, in association or not with other factors. Among functional nervous affections not even hysteria can claim more varied possibilities. Tremors and tics, pseudochoreas, insomnia, and headache are all within its sphere of action. A most striking limitation, remarkable by contrast, appears in the

*Read before the Hudson County (N. J.) Medical Society, February, 1904.

field of peripheral nerve diseases. Within my knowledge, which I believe to be quite in accord with the general consensus of opinion and belief, neuritis, except of the cranial nerves, is quite rarely due to lues.

With an enemy so active, so versatile, so protean in its kaleidoscopic appearances, presenting such varied and inconstant symptom pictures, it would appear to be well-nigh impossible to always, or even often, penetrate the disguise, see through the mask and recognize positively this particular foe. And yet the difficulty is more apparent than real. There are certain peculiarities of conduct, certain earmarks, which are individually suggestive and in association, collectively, constitute a syndrome which, in my experience, is almost pathognomonic. Tested again and again in many hundreds of cases, during the past fifteen years, I have learned to rely with confidence upon its value. *Given a patient between the ages of twenty-five and forty-five, affected with any form of intracranial paralysis, which was preceded by headaches, of nocturnal onset or exacerbation, associated with vertigo and with insomnia, the insomnia occurring during the first half of the night, the paralysis developing during sleep, both headache and insomnia disappearing upon the onset of the paralysis; the cause is syphilis.*

Some little elaboration of this formula may prove advantageous: The age limit specified, for example, should not be adhered to too literally, in that both younger and older patients may occasionally be included. The average age among 160 carefully recorded cases of cerebral syphilis was thirty-seven; the youngest was twenty-two, the oldest seventy-two. The average interval in years between the primary syphilis and the meta-syphilitic nervous accident was seven and one-half years; the shortest interval was seven months (this patient, a case of paraplegic myelitis, being at the time and having been continuously from the time of the initial lesion, under active and most intelligent treatment), the longest interval was twenty-eight years. Only a small percentage of cases of the primary disease are found in patients under the age of eighteen; we do not therefore, expect nervous accidents until six or eight years later. Beyond forty-five or fifty, retrograde tissue changes are beginning, especially arterial degenerations, the cerebral symptoms resulting therefrom somewhat and in some ways, resembling more closely than when younger, those of specific disease.

The headaches vary widely in location and intensity and only rarely possess any diagnostic significance in either of these two particulars. An excruciating, agonizing headache, inducing a semi-maniacal excitement or hallucinations, is suspicious, but points as strongly toward tumor as toward syphilis. Local pain or tenderness may also be suspicious, but it cannot be interpreted with any positiveness. The striking and quite constant feature of a specific headache is its nocturnal periodicity and its persistence. Of the 160 cases quoted 141 had suffered from decided and more or less persistent headaches, and of this number 124 were affected with headaches having an evening onset, increasing toward night, most of them being free from any discomfort during the morning. When followed by cerebral paralysis, these headaches invariably disappear, at least for a time, and a recurrence is to be interpreted as a danger signal, indicating a renewal of hostilities on the part of the enemy. Vertigo is of significance only when present with the headache, an association which is quite constant. It is usually a position vertigo, worse on rising or stooping. Excitement or exposure to excessive heat will also aggravate or provoke it. It is not, as a rule, accompanied with tinnitus, deafness or nausea, is subjective rather than objective, and is dependent presumably upon vascular wall changes. It occasionally merges or lapses into transient unconsciousness.

Some disturbance of sleep is almost invariably present during the developmental period of intercranial syphilis. Broadly speaking, the younger the patient, the greater the tendency to insomnia; the older the patient, the more marked the morbid somnolence. Under fifty, insomnia is the rule, with few exceptions; if over fifty, the rule is somnolence. Insomnia is distinctly associated with and a forerunner of motor or sensory symptoms. Somnolence indicates an impending mental involvement, usually a dementia. Insomnic syphilitics lie absolutely awake during the first half of the night, melancholiacs the last half, and neurasthenics sleep lightly, wake often, sleep again, and dream much. The degree of insomnia in nervous syphilis bears something of a ratio to the intensity of the headache. Occasionally there is wandering nocturnal delirium or hallucinations. Abruptly disappearing with the headaches upon the onset of paralysis, the return of either, singly or together, possesses the same warning significance.

The tendency of syphilitic paralysis to develop during sleep is to me an interesting and enlightening observation. That it is a fact is abundantly attested by a large number of recorded instances among my cases. Nervous syphilis, like some other enemies of mankind, is a creature of darkness, active at night. Witness the nocturnal headaches, insomnia, delirium, and finally the paralysis. In so far as the paralysis is concerned, an explanation which seems to me quite plausible is that the lesion, usually being an obstructive endarteritis, the tendency to occlusion from thrombus or otherwise is greatest during sleep, the heart's action being less, dynamically, and the vis a tergo greatly reduced. When paralysis develops during the day in a syphilitic patient, up and actively about, it suggests ruptured aneurysm rather than thrombus. An explanation for the final proposition of the diagnostic syndrome is not so easy. Disappearance of the headache and of the insomnia abruptly upon the onset of the paralysis is a fact none the less, and of such frequent and almost constant occurrence as to make it distinctive.

For fear of misunderstanding, let me add just here first the statement that this syndrome applies to acquired cerebral syphilis peculiarly, to a much less constant degree to spinal syphilis, and scarcely at all to hereditary syphilis. Let me say further and with emphasis, that its value depends not upon any one, but upon the association of all, the symptomatic conditions enumerated. Careful study and application of this syndrome offers the possibility of preventing the explosion—of forestalling the accident. Persistent nocturnal headache with associated insomnia, properly interpreted and properly treated, should not be followed by paralysis at all or other explosive accident.

Other presumably familiar signs by which we are assisted in recognizing a syphilitic origin for intracranial palsies might be appropriately recapitulated just here. Chief of these signs is the fact of an erratic, sometimes a bizarre, distribution in the paralysis, due to the fact that, as a rule, there are more lesions than one. Fugacious preliminary palsies or paresthesiæ, coming and going for days or weeks before a final culmination, is also highly suggestive. A well-known selective affinity on the

part of syphilis for certain regions and tissues can also be utilized with advantage. The ocular muscles, and especially those supplied by the third nerve, are so prone to syphilitic attack that a ptosis or strabismus, occurring suddenly in an adult, especially if preceded by headaches and insomnia, may be put down at once and quite safely as due to this cause. Localized tremors in the regions subsequently to be paralyzed are quite often observed. Finally, a general malaise with mental inertia, and sometimes a cachectic appearance, not explained by any condition of the kidney, liver, or other viscera, are of some significance in association with others of the symptoms mentioned.

Before discussing the subjects of prognosis and treatment, which latter especially demands but little space because of its simplicity, I should like to recapitulate briefly the practical and often vitally important advantages to be derived from the possession and application of this diagnostic formula: It renders the attending physician independent of the many sources of error and confusion, ignorance and misrepresentation incident to ordinary methods in obtaining a history. You are the more promptly enabled to identify the cause and to begin the proper treatment. It enables you often to modify favorably a prognosis which would be otherwise far worse. Finally, and most important of all, its application will, many times, serve to forestall an explosion, warning the initiated of the storm that is brewing, in ample time for prevention.

The prognosis in syphilitic disease of the central nervous system varies widely, and in a considerable majority of all cases, the outcome cannot be predicted with any certainty in advance of at least some initial response, or lack of it, to specific treatment. Meningitis, gummatous tumors, many cases of myelitis and paralysis due to thromboses or endarteritis obliterans, offer a decidedly favorable prognosis, especially in contrast with these same conditions when due to other causes. On the other hand, locomotor ataxia, specific in origin in from 60 to 90 per cent. is never cured, and but rarely modified except for the worse, by any form of specific treatment. Epilepsy caused by syphilis, if it is to be cured by mercury or iodides, must be recognized and treated promptly, for once the habit is well established, the cause, no matter what it may be, becomes of minor importance, so far as cure of the epilepsy is concerned. Epileptics, syphilitic or not, are relatively intolerant of iodides. In general paralysis of the insane, no matter how clear the history of previous infection, nothing positive can be promised as to the final outcome. I have seen several examples of so-called pseudo-paresis clear up under large doses of the iodide, with or without mercury, these cases not differing essentially in symptomatic details from others which steadily progressed from bad to worse under the same treatment, and with the same etiological history. Promptness in recognizing the underlying cause is a most important factor. No matter what or where the lesion, if it prove destructive, the consequences are permanent. In a large proportion of the cases of intracranial syphilis, the lesion is an endarteritis with proliferative thickening of the intima and proportionate gradual reduction of the lumen of the vessel, an endarteritis obliterans. If the obstruction is not complete (and it rarely is at first) much can be done—indeed everything—in many cases by prompt active treatment.

The treatment of intracranial syphilis, is, as I have stated, quite simple so far as drugs are concerned, and yet a certain nicety of adjustment and familiarity with certain details in the technique, so to speak, are quite important. Two drugs only are of any positive constant curative service, potassium iodide and mercury—of the two, I place infinitely more dependence upon the iodides, and if compelled to make choice between them, should not hesitate a moment in my selection. Mercury is, however, sometimes of service, and in a few cases of more decided service than the iodide. In my own work I have found mercury to be indicated, rather than the iodides, the nearer the nervous invasion is to the primary disease; the longer the interval between the chancre and the paralysis, the more positive the indication for and benefit from the iodides. I use mercury by inunction altogether in my work, employing it almost as a matter of routine during the intervals or interruptions in the use of the iodide. In giving potassium iodide I have, for many years, taught the doctrine that there is no such thing as a fixed or arbitrary dosage. When indicated, give it not with iodism as a guide, but until either the disease yields, or until very large doses—seven, eight, or nine hundred grains daily—without any modification of symptoms, satisfies you that its further employment is useless. To recur to iodism, that stumbling-block in the pathway of so many. Iodism should be a very rare obstacle to the successful treatment of nervous syphilitics. I have had to discontinue the drug in only two cases during the past six years, a success due, I believe, entirely to my method of giving the iodide, which is as follows: I always use the drug in the form of the saturated solution, for convenience and accuracy. I am careful to get a pure drug from a reputable chemist. Beginning with twenty drops (never less) after meals, the dose is increased three, five, or ten drops daily, according to the urgency or gravity of conditions. The vehicle is changed every third day, the first two days water, the next two milk, the next Vichy, then Apollinaris, then back and through the same cycle again and again, the amount of the vehicle being increased *pari passu* with the increase of the drug. Should iodism develop to an annoying or extreme degree, I stop for two days and then start just where I stopped, doubling the ratio of daily increase. Your patient will be thirty or forty grains daily further along before iodism recurs, employing this method. The addition of essence of pepsin in two or three-drachm doses after the iodide seems to be of decided service at times. The rennet mixture advocated by some writers is a vile mess, in my judgment, and is but rarely tolerated for more than a few days. Iodism is much more apt to occur from the continued use of a fixed dose, although a moderate one, than when giving it by the progressive method. I have seen iodism from continuous 20 gr. doses disappear at forty or fifty grains—paradoxical as this statement may appear. Following this method I have repeatedly given six hundred grains and more daily without any special inconvenience, and in one patient affected with meningomyelitis, a daily quantity of 1245 drops of the saturated solution was reached without untoward symptoms.

105 West Seventy-third Street.

Palpation of the Abdomen in the Warm Bath.—Sticker calls attention to this method which he has been using since 1891. By placing patients in a bath of warm water muscular relaxation is promoted to an almost incredible degree and palpation of the internal organs can be practised with remarkable ease. Recourse to this maneuvre frequently permits information to be obtained which otherwise would necessitate an exploratory laparotomy or at least examination under ether.—*Zentralblatt für innere Medizin.*

CLAUDIUS' CATGUT.

A NEW AND EFFECTIVE METHOD FOR ITS STERILIZATION.*

By ALEXIS V. MOSCHCOWITZ, M.D.,
NEW YORK.
ADJUNCT ATTENDING SURGEON, MOUNT SINAI HOSPITAL.

THERE exist at present so many different methods of preparing catgut for surgical purposes, that no testimony is required to prove that the ideal method has not yet been discovered. It is, however, my belief, that the method of preparation as outlined by Claudius,[1] is so far in advance of all other methods in vogue, that it deserves to be termed at least a good attempt at the ideal. Catgut prepared by this method has been in use almost uninterruptedly during the past seventeen months at Mount Sinai Hospital, for all purposes for which formerly catgut prepared by other methods had been used, and it has stood the test so well, that it will perhaps be pardonable, if I again call the attention of the members of the Surgical Section of the Academy to this method.

An ideal catgut should have the following attributes: (1) It should be absolutely sterile. (2) In the course of preparation it should not lose any of its tensile strength. (3) It should be readily and simply prepared, and without undue expense. (4) It should be absorbed completely, but only after it has served the purposes for which it was intended.

Let us now see how far the catgut of which I speak responds to these four requirements:

Sterility.—My experience with this catgut is limited to its actual use in practice, as we have not made any but the simplest culture tests. The original article of Claudius was so convincing to me at the time, that I thought the method deserved at least a cautious trial. I am pleased to be able to say that examinations by Martina[2] and v. Hippel[3] have brought additional very strong experimental testimony in order to prove the sterility of the catgut. Claudius used for his preliminary experiments some very resistant spores from garden earth; Martina, on the other hand, experimented principally with anthrax spores, and he found an absolute sterility after an exposure of only thirty-five minutes. As, however, there exist certain spore forms even more resistant than those of anthrax, though they are not pathogenic to the human organism, it is wisest, perhaps, to expose the catgut to the action of the iodine solution for eight days, as originally proposed by Claudius.

This much for the sterility of the iodine catgut; but this catgut has an additional and most important qualification, which is, that it is not only aseptic, but owing to its imbibition with iodine, it is also highly antiseptic. Accidental contact infections happen more frequently than one would suppose in all operating rooms, and the infection of catgut is very probable, when a ligature is handled for the purpose of tying it, because as it is passed and handled it rubs off some of the more superficial layers of the operator's epidermis and may become infected from the deeper layers (it is needless to say that this occurs only when operating without gloves). But in such case any germs adhering to the catgut will be efficiently rendered sterile by the iodine.

As already stated, my experience is limited to the practical utility of this catgut. We have used it now for over seventeen months, in all varieties of operations, and we can assert without the slightest hesitancy that our results as regards aseptic healing were fully as good and perhaps better, than when we used sublimate-alcohol catgut. Though at first we used it only very cautiously and hesitatingly, we now use it for all operations without exception, upon any and every part of the body, where we find an indication for the use of catgut.

Tensile Strength.—I regret to say, that I have not as yet arrived at a definite conclusion regarding the second requirement. Claudius claims that the tensile strength of the iodine catgut depends upon the original quality of the catgut, *i.e.* the better the catgut originally, from a standpoint of tensile strength, the better it will be after its preparation, and in addition he also claims an increase in the tensile strength, if the prepared iodine catgut is immersed prior to its use into a 3-per-cent. solution of carbolic acid. Martina, on the other hand, claims that there is an increase in the tensile strength, if prepared by the iodine method alone—after many tests he arrived at the conclusion that the increase is approximately one-seventh of its original strength. Our experience is not quite so favorable, as we have noted a slight loss in the tensile strength, particularly with the heavier grades. I have paid much attention to this point, and I do not believe I am in error when I say that the brittleness occasionally found is due to improper methods of preparation; either the iodine solution was too weak or the catgut was permitted to remain in the solution for too long a time. At all events the loss of tensile strength, if any, is very slight, certainly not sufficient to mar its utility.

Method of preparation.—The preparation of this catgut is simplicity itself. Catgut, just as it is bought from the dealer, is wound, preferably in a single layer, on to the spool, and tied at both ends, in order to prevent unraveling. It is then immersed for eight days in a solution of iodine, 1 part; iodide of potassium, 1 part; distilled water, 100 parts. (The solution is prepared by dissolving the iodide of potassium in a small quantity of the water, to which the iodine, previously finely pulverized, is added, and the whole diluted up to 100 parts.)

Originally, I confess, I lacked the moral courage to use the catgut as bought from the dealers, and therefore I primarily removed the fat with ether, but later on I gained more confidence, and we now use the catgut without any preliminary preparation.

As already stated, this catgut has been found to be sterile even after half an hour's exposure, but, to be absolutely sure, it is perhaps, wisest not to use it before the lapse of eight days. It is preserved without any change in the original solution. It will keep sterile forever, certainly at least as long as the strength of the iodine has not been reduced materially by evaporation. As, however, it has been found that if kept too long, say over half a year, it loses some of its tensile strength, it is wise to prepare at one time only so much as can be used up in six months.

When using it, Claudius recommends that it be rinsed off either in sterile water or in a 3-per-cent. solution of carbolic acid. Martina recommends that it be used directly, without any intermediate solution, as he wishes to avoid a diminution of the iodine strength. We use ordinary sterile water. Any unused catgut is replaced in the original solution, and may be used again in half an hour, or if it is feared that it may have been virulently infected, it may be left in a separate vessel for another eight days.

I am sure you will readily agree with me, that the method is as simple as it can be; it is certainly very cheap, one gallon of the solution, requiring 608 grains of iodine, and an equal amount of iodide of potassium, costs only 42 cents; and as it is not necessary to waste the least bit of catgut, the cost of the method is still more reduced.

*Read before the Surgical Section of the New York Academy of Medicine.

It is important to keep the solution in well-stoppered bottles or jars, because the iodine is volatile, as can be seen by the purple color of the air covering the solution, and in time it deteriorates. Solutions good enough to use should have a deep-brown, almost black color; any solution not corresponding to these physical requirements should be discarded.

Catgut prepared according to this method is of a deep-brown, almost black, color, and still retains the characteristic odor of iodine; it is perfectly smooth, not swollen as one might expect from its immersion in an aqueous solution; it is very strong, yet soft and pliable, and is exceedingly convenient to use, inasmuch as it does not kink or curl up, like catgut which has been kept in alcohol. It has been compared to a fine copper wire, but I think a better comparison would be with a waxed shoemaker's thread.

Absorption.—Regarding the fourth point, I can also speak only from a practical standpoint; the knots stay tight and do not tend to untie or loosen, and we have seen no untoward symptoms which could be traced to a too early absorption. Martina is of the opinion that it is absorbed somewhat more quickly than catgut prepared by other methods, though I do not see on what he bases that assumption, as even his own experiments appear to show that its absorption is slower; at all events we might safely say that there is no great difference either way. This has also been the result of experiments by v. Hippel.

I believe I have now amply proven the superior advantages of this catgut; it is only right, however, that before concluding I shall speak also of its possible disadvantages, and also to refute some of the objections, which might be raised by the more skeptical.

The first question which might be raised is regarding the toxic effects of the iodine introduced; there need be no fear on this account, because (1) even in the most extensive operation the toxic dose can never be reached, and (2) the iodine is divided so minutely that it quickly enters into a chemical combination with the salts of the body fluids, and forms only the innocuous iodides, etc.

Another question which might be raised is, whether the iodine does not act as an irritant. Personally I have never seen such an occurrence, and cannot see how it could occur, for reasons already stated, viz., that the iodine enters into a chemical combination with the salts of the body fluids. It is true that it may act as a slight irritant to the skin, but my experience in this respect is limited, as I do not find any necessity for absorbable skin sutures. Just for the sake of experiment I have used it lately in all cases of skin suture, but found no irritation to result from its use.

The odor of the catgut might be objected to, but this is so trivial a fault that it hardly needs refutation.

Practically the only valid objection I have found is that, owing to the volatility of the iodine, it has a kind of oxidizing action upon metallic instruments. Of course I do not mean during the short space of time that it is in actual use, but only if it is kept in an instrument cabinet; but this inconvenience is so readily obviated that it barely merits consideration. The same is true of the stains which it may cause on linens.

In conclusion I will only repeat that we have used this catgut continually during the past seventeen months at Mount Sinai Hospital, and it has always given us perfect satisfaction. Very little has been written on this subject, but what has been written is uniformly in its favor; reference is here made only to the publications by Claudius, Martina, v. Hippel already mentioned, to that of Senn,[4] and more particularly to the latest article of Claudius,[5] in which the clinical experiences of various surgeons of Denmark are given. I believe this method of preparing catgut to be a distinct advance, and take the liberty to bespeak for it a more extended trial.

A CASE OF HODGKIN'S DISEASE TREATED BY X-RAYS.

By EDWARD B. FINCH. M.D.,
NEW YORK.

R. W., male, eighteen, single, had had the usual children's disease, but otherwise was in excellent health up to about two years ago, when he began to suffer with pains in his left shoulder and arm; these kept increasing in severity for some six months, when a swelling was noticed over the cartilage of second rib on the left, not tender to pressure and with no constitutional symptoms. In February, 1903, he was sent to Dr. C. L. Scudder of Boston for operation. At that time physical examination showed the patient well developed and nourished. The heart and lungs were normal with the exception of an area of diminished resonance anteriorly over the base of the heart, extending up to the sternum and half an inch to the right, to two and five-tenth inches to the left of the bone. An indefinite mass could be felt at the sternal notch. Over the cartilage of the second rib was a soft tumor about two inches in diameter, not tender or painful. The spleen was not enlarged. Urine, pulse, respiration, and temperature were normal the only time the patient was seen. Blood examination by Dr. T. F. Lord showed: "Hæmoglobin, 70 per cent.; red corpuscles, 720,000; white, 23,000. Polymorphonuclear neutrophiles, 84.4 per cent.; large, 5 per cent. Basophiles, small, 7.6 per cent.; oxyphiles, 2 per cent.; mast-cells, 1 per cent.

"Red cells normal in size and shape, good color, no nucleated forms. No malarial parasites. Blood plates normal in number. Only abnormality of above is white count of 23,000 with very slight secondary anæmia. Two forms of leukæmia (splenic myelogenous and lymphatic) are ruled out. Most obvious diagnosis is pseudoleukæmia or Hodgkin's disease. Increase in white-blood count may be due to some inflammatory condition in the growth. A moderate leucocytosis as is present here is not uncommon in Hodgkin's disease. Clinical findings, together with blood, suggest lymphosarcoma of the thymus or anterior mediastinal glands."

Dr. Scudder made an incision into the tumor, but finding it could not be totally removed curetted out only a portion of tumor to behind sternum into the anterior mediastinum.

"*Pathological Examination.*—The specimen consisted of several small, irregular bits of yellow, necrotic-looking material and muscle with which the growth appeared to be infiltrating.

"*Microscopical Examination.*—The specimen was for the greater part more or less necrotic, but in the better preserved places the recticulum was increased. The most striking thing was the number of eosinophilic leucocytes present which, in many fields, constituted about one-half the cells. The others were lymphocytes and large cells with irregular nuclei. Many giant cells with reticular nuclei, irregularly placed, were also present. Many forms of degenerated cells were seen, and most of the

fields showed a few leucocytes. Vessels were fairly abundant. A guinea-pig was inoculated subcutaneously with a bit of the tumor on February 10 and died of unknown causes February 26. An autopsy showed an abscess at the seat of inoculation and hyperplastic glands in both groins. No tubercle bacilli could be demonstrated microscopically."—(From a "Pathological analysis of nine cases of Hodgkin's disease," by Channing C. Simmons, in which this case was included).

On July 23, 1903, Dr. F. H. Zabriskie of Greenfield, Mass., sent the patient to me with the diagnosis of Hodgkin's disease, with the request to try the effect of the *x*-ray, having given the iodides, arsenic, and iron a thorough trial with no good results. The patient had every appearance of severe suffering. His complexion was sallow, his eyes dull, his shoulders stooping, and he carried his left shoulder and arm in a fixed position, avoiding movement as much as possible. Over the manubrium sterni and to the left was a soft protuberance about three inches at the base and projecting half an inch, exquisitely tender with a crescent-shaped somewhat hypertrophied scar below, about four inches in length, with a small discharging sinus at the right end, the site of former operation. The lymph glands were enlarged in the neck, axillæ, and groins, from very small, to about three-eighths of an inch in diameter. The spleen was enlarged, but could not be felt below the border of the ribs. The fluoroscope demonstrated beautifully the presternal tumor and the enlarged spleen. Heart, lungs, and urine were normal. At the suggestion of Dr. W. J. Morton the patient was given quinine, though in smaller doses than he recommended, 3 grs. being given three times a day, during the *x*-ray treatment. In addition he was given tonic doses of iron, arsenic, and strychnine. Exposures to the *x*-ray were begun on July 23, a very high tube being used. Each sitting lasted from forty to ninety minutes, the tube being moved at intervals of ten minutes, so that the patient was given practically a general bath in the *x*-ray at each sitting, in accord with the theory that Hodgkin's disease is a disease of the whole lymph system and not of isolated groups of glands, the face and scalp alone being screened off. The exposures were kept up almost daily to September 7. Then followed an intermission of two weeks with only one exposure. The pain in the tumor and shoulder disappeared after the fourth exposure, but slight pain recurred when patient overexerted himself, up to the fifteenth exposure, when it permanently disappeared. On the eighth exposure the glands were markedly smaller and on the fifteenth exposure the cervical glands could not be felt. The presternal tumor gradually decreased in size, and on the sixteenth exposure could scarcely be seen, and on the twenty-ninth exposure, August 28, was imperceptible. The sinus ceased discharging during the first days of treatment and at this time was completely healed, and the hypertrophied tissue in the scar had disappeared. On September 18, exposures were stopped owing to dermatitis, which was not severe, and were not resumed until October 13, and were then kept up until November 3, when the fifty-sixth exposure was made. At this time nothing abnormal could be found in the patient, and he was not seen again until November 30, when exposures were resumed and kept up daily till December 5, when the sixty-second exposure was made. At this time the patient seemed to be in perfect health in every way; looked well, felt well, and weighed 150¾ pounds, a gain of 14 pounds since treatment was begun.

On October 19, at the time of the forty-fourth exposure, Dr. Harlow Brooks made a blood examination and reported as follows: "Hæmoglobin, 86 per cent.; red corpuscles, 3,552,000; leucocytes, 9,200; clot formation, slow but complete; blood plates, few.

"The red corpuscles show slight variation in size and poikilocytes are infrequent, no cells showing cytoplasmic degeneration are present, and no nucleated red corpuscles were found. The erythrocytes are notably deeply stained with hæmoglobin, more so than in the ordinary specimen of normal blood. No malarial organisms are present. The differential leucocyte count shows the following: "Polymorphonuclear (neutrophiles), 87 per cent.; lymphocytes, 6 per cent.; mononuclears, 2 per cent.; eosinophiles, 3 per cent.; basophiles, 0.

"You will notice that while there is no leucocytosis, in the strict sense of the term, the leucocytes are relatively numerous as compared to the number of red corpuscles. This relative increase is, however, in the polynuclear elements, and not in the lymphocytes, as was the case in the previous examination; in fact, there is nothing about the blood which would indicate Hodgkin's or lymphatic leukæmia, for the mononuclears are all relatively below the normal. I am inclined to account for the increase in the neutrophiles as a result of the action of the *x*-rays, for I have seen a similar condition in other cases where the rays were applied in altogether different condition."

During the first two weeks of the *x*-ray treatment the patient's temperature fluctuated within a range of from ½° to 1° F. daily, but after that did not vary from normal.

In spite of the long exposures, only twice a dermatitis of any moment set up; the first of the first degree which lasted only five days; the second of the bullous variety, confined to the axillæ and lasting ten days. The body was kept thickly dusted with stearate of zinc to prevent irritation from the clothing.

At the present time, January 6, there is still a marked tan over the whole trunk; otherwise the patient seems perfectly normal in every way.

The case is reported as one of Hodgkin's disease. The clinical picture was of that disease. The blood analyses exclude leukæmia. Tuberculosis and syphilis were excluded. The only other disease to be considered is sarcoma, toward which the increase in the percentage of the polymorphonuclear neutrophiles would point. However, the pathological examination showed only one kind of tissue attacked, the lymphadenoid, and it extended from one group of glands to another without infiltration. Until a more exact line can be drawn between the two diseases, it seems fair to class this condition as Hodgkin's disease.

The use of quinine as an adjuvant to the *x*-ray, on Morton's theory of its fluorescence in the blood, undoubtedly hastened the favorable result in this case, several cases of Hodgkin's disease having been reported as unsuccessfully treated with the *x*-ray when quinine was not used.

Addendum.—On March 12 the patient returned, presternal tumor having recurred, being almost as large as when first seen in July. No adenopathies could be detected. The pain in tumor and right shoulder was severe. A blood examination, made by Dr. Lord on March 10, showed little difference from that made a year ago, except in the reduction in the white count from 23,000 to 12,000 and the loss of about 1,000,000 red cells.

Exposures to the *x*-ray were given daily to April 2, twenty-one in all. At this time the tumor had entirely

disappeared and the patient seemed to be in perfect health. Fluorescin was used in addition to the quinine as an adjuvant to the *x*-ray. From the marked action of the *x*-ray treatment it does not seem too much to hope that in time the disease will be completely eradicated.

LOCAL APPLICATIONS IN PNEUMONIA.

By W. F. CHURCH, M.D.,
GREELEY, COL.

The seeker after specific remedies can but deplore the present unsettled methods in the treatment of pneumonia. Opinions as to the best course to pursue seem to be as varied as was the case twenty or thirty years ago, and results are but little if any better.

The fact that the disease is now generally accepted as an infection by pneumococci has, of course, produced new lines of treatment with the intention of inhibiting the action of the germ and thus prevent the development of toxins. So far results do not seem to show improvement over old methods.

The ideal remedy has yet to be produced. Is there not now, however, one line of treatment better than all others, or can equally good report be made from several remedies? Some medical teachers advise the use of arterial sedatives; some the use of a drug like digitalis to produce more forcible contractions of the heart; others drugs to act as germ antagonists in the blood; while still others state that the course of the disease is practically uninfluenced by any remedy. It is not the purpose of this paper to attempt to prove that one of these methods alone is correct, but they are here considered in their relations to local treatment.

It is probable that the status of local applications would have been settled long ago had the profession been united on a particular mode of internal treatment. At a time when radical measures were employed, blistering was considered a very necessary part of the treatment. This was largely superseded by poultices of different kinds, the ice-bag, or the cotton-jacket. While the jacket was used to maintain an even temperature, and not otherwise expected to influence the course of the disease, it is now apparently much less used than formerly. A gradual change from severe to mild measures has led to the non-use of any for uncomplicated pneumonia by a majority of the leaders in medicine. Notwithstanding this, local applications are still quite widely used.

In a disease so fatal as pneumonia the medical attendant naturally feels that every resource should be brought to aid in the patient's recovery. In many other parts of the body applications over the part affected seem to be efficacious. If so, why will not the inflammatory process in the lung yield to similar treatment? This may be the line of reasoning pursued without stopping to inquire if supported by anatomical and physiological facts.

If local applications are valuable in every case of pneumonia, even during a certain stage only, it ought to become an established fact in medicine. If they are unnecessary, and fail to modify the course of the disease, it is injurious to those trying to work along reasonable and scientific lines to meet with the influence of their continued use.

To determine whether this question belongs in the domain of empiricism only, or can be satisfactorily solved by physiological laws, it is best to consider briefly the relations of the lungs and their blood and nerve supply. They are not connected with the protecting chest wall, except by means of the pleura, and in this way quite indirectly, as the outer side of the outer layer is in contact with the connective tissue while the inner side of the inner layer is in contact with the lung. A moment's reflection should be sufficient to satisfy one that any transmission of blood from the lungs to the muscles and integument of the chest wall, or *vice versa* through the medium of the pleura, must be very slight indeed.

Unlike other organs, the lung has a double circulation, the *nutritive*, and also a *functional* one. The pulmonary arteries convey the blood from the right ventricle to the lungs for purposes of aëration, to be returned by the pulmonary veins to the left auricle. The bronchial arteries which are given off from the thoracic aorta follow the bronchi and supply blood for nourishing the lungs. A plexus from this source on the mucous coat communicates with the pulmonary arteries and empties into the pulmonary veins. Branches also ramify upon the surface of the lung underneath the pleura. The bronchial vein on the right side terminates in the vena azygos major, and on the left side in the superior intercostal vein. Blood is thus sent to the lungs from both ventricles and received from there by both auricles. The nerve supply is furnished by branches from the pneumogastric and sympathetic.

The only logical conclusion that can be drawn from the foregoing is that in order to modify the blood supply to the lungs the agent must act upon the heart itself, or the vessels connecting the two organs. It is supposed and claimed that the main action of local applications is directly on the lung. How can this be? Counter-irritants, heat and cold, and the glycero-clay mixtures vary somewhat in action, but are supposed to be chiefly beneficial by producing hyperæmia of the integument. It is claimed for the cold compress or ice-bag, and possibly other agents, that a reflex action is produced affecting the cardiac and respiratory centers.

Dilating the cutaneous vessels, and perhaps at the same time anæsthetizing the peripheral nerve twigs, may relieve the pleuritic pain which so often accompanies pneumonia, but the small amount of blood drawn to the integument will not relieve the lungs more than would an equal quantity drawn to other parts of the body, as in any case it must be taken from the general circulation and not directly from the lungs.

W. Gilman Thompson has demonstrated, by means of specially conically constructed thermometers, inserted for six or eight inches into the thorax by way of sinuses resulting from chronic empyema, that poultices, applied as hot as could be borne, or ice, modified the temperature in the lung no more than one-eighth of one degree. With no greater effect than this, it can hardly be expected that these agents will influence the inflammatory process in the lung. The claim that local applications by reflex action of the cutaneous nerves modify the course of the infectious process is difficult of proof. Musser says: "The cold compress stimulates the peripheral nerve-endings and reflexly the nervous mechanism of heart and vessels and of respiration." He does not claim this of heat in any form. If such stimulation takes place there is good reason to suppose that it is through the sympathetic and not the pneumogastric and phrenic nerves. A majority of physicians think that the heart is already overstimulated during the stage of congestion and beginning consolidation, and that any measure that will increase the strength

and action of the heart-beat is contraindicated. Can we expect that more forcible contractions of the heart will better force the blood through a consolidated portion of lung with perhaps adjoining congested areas, or will it make the condition worse? Stimulation to the cardiac and respiratory centers should be chiefly valuable when they are showing the effects of marked toxæmia. It must not be forgotten that cold, especially if long continued, will produce anæsthesia of the cutaneous nerves, and reflex action will be abolished. The author quoted does not apply the compresses oftener than from one-half to two hours, and some of the objections to applications are avoided, and he really gets, especially if there is considerable temperature, the alternate action of heat and cold. If the author is correct in his claims, the remedy is chiefly valuable in selected cases. Thompson, however, claims that "it can scarcely be maintained that any deep-seated reflex effect called into play through external applications of heat or cold independently of direct transmission of thermal units, is capable of controlling an inflammatory process in the lung.

At times there may be decided objections to almost any form of external applications, as they may not only fail to help but be positively detrimental by preventing the patient from getting the rest and sleep necessary to recovery. If heat or cold is used the frequent changes necessary to maintain an equable temperature disturbs and practically prohibits sleep, and even mental calm, and yet these are very important essentials to a favorable outcome. The addition of any appreciable weight to the front and sides of the chest must result in loss of strength, for the muscles are obliged to raise it the distance of the expansion upward and outward during inspiration. I once saw a child three years old whose chest was covered with one-half pound of one of the popular preparations. The respirations were 60 to the minute, so the child was lifting the distance the chest moved 30 pounds every 60 seconds, 1,800 pounds in an hour, and over 20 tons in a day. Every unit of strength was needed by the little sufferer to fight the intense toxæmia present, and yet it was recklessly wasted in raising a chest weight which to careful observations had no effect whatever on the disease, and certainly not on the outcome, unless to hasten it.

By baths with friction, rubefacients, etc., more blood can be drawn to the extremities to relieve internal congestion than would be possible by producing hyperæmia of the chest wall.

In conclusion, it may be said that the chief value of local applications is for the relief of pleuritic pain, and that one should usually be selected which affords the most comfort to the patient. When this pain is relieved the service of the application is ended, and it should be discontinued. The cold compress may possibly be of some value in selected cases.

Spontaneous Gangrene of the Hollow Viscera.—This topic is exhaustively discussed by Roswell Park, who emphasizes the statement that in the presence of sudden and acute symptoms, which include intense abdominal pain, collapse, and rigidity of abdominal walls, very little time should be wasted in speculation as to the character of the lesion. This trial of symptoms constitutes a reliable and exacting demand for abdominal section, followed by such suitable measures as the case may permit. No such case as would be lost without an operation would be lost in consequence of it, while every such case must, without it, of necessity prove fatal.

Pipe Smoker's Ulcer of the Hard Palate.—Two cases are reported by A. Rupp who advises the following plan of treatment: (1) The dentist should look after the teeth, to remove tartar and to fill up cavities. (2) After taking food or drink of any kind the mouth should be thoroughly rinsed with a simple salt solution, and the teeth brushed. (3) To the ulcer should be applied, by the patient, at intervals of two hours through the day, a solution of menthol in absolute alcohol (one drachm to the ounce). —*Laryngoscope.*

Spasmodic Asthma.—Arthur T. Wilkinson saw great improvement from the administration of Fowler's solution, mjiii increased to mxv t. i. d., and continued for several months. He finds no advantage in giving hydriodic acid over potassium iodide. For acute attacks, he speaks highly of hot applications between the scapulæ and chest, and also of the nitrates, especially the potassium salt. He finds no advantage in combining it with belladonna. In the nitrites he has been disappointed, and speaks strongly against the use of chloroform or morphine, except in selected cases.—*Medical Chronicle.*

Ultramicroscopic Organisms.—J. J. MacKenzie discusses the existence of organisms which are too small to see with the strongest microscope. Those which have so far been discovered are all parasitic, and thus experiments can be made by animal inoculation and the presence of the hypothetical parasites demonstrated by the disease produced in the animal. Besides, there are filters which can successfully filter out the vast majority of known bacteria. The pores of these filters are so small that bacteria cannot be washed through them. It is by a combination of the method of animal inoculation and filtration through such a filter that these organisms have been discovered. Practically the first knowledge which we have of such minute creatures resulted from the work of Loeffler and Frosch upon foot-and-mouth disease. The contagion, whatever it is, is present in the serum which is found in the vesicles of this disease. Microscopical examination of this fluid does not reveal any organism, although a minute quantity of it was sufficient to infect other animals. The fluid was equally contagious after passing through a filter. In order to show that they were not dealing with an excessively virulent soluble poison, these workers diluted the lymph and passed it through the filter and inoculated an animal with it. From the vesicles which developed upon this animal they collected the lymph, refiltered and inoculated a second animal, and so on through a series of six animals. The amount that the last animal would have received if it had been a poison, would have been far below the infecting dose. Nocard and Roux have discovered another of these organisms in the so-called contagious pleuro-pneumonia of cattle. By the microscope it was possible, however, to see enormous numbers of minute dancing points. This was a parasite just upon the border of visibility. The writer mentions several other diseases of domestic animals which are to be classed as due to ultramicroscopic organisms. The most important of these viruses, as far as man is concerned, is that of yellow fever. As to whether these organisms are simply very small bacteria, it may be said that there is a marked uniformity of size among bacteria. There has not yet been met an ultramicroscopic organism of a non-pathogenic character. The writer believes that the virus of contagious pleuro-pneumonia is the only one of this group that can be assigned to the bacteria. This is just visible and can be cultivated outside of the body. The thermal death point and the effect of disinfectants on these ultramicroscopic parasites do not differ materially from those of the higher and larger bacteria. Much clearer light must be thrown upon the subject before these invisible parasites can be definitely placed in the scale of organized being, and the difficulties in the way are very great—their minute size because we do not yet know how to cultivate them, and because they are all parasites and can be studied only in the living organism.—*The Canada Lancet.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

ETIOLOGY OF SMALLPOX.

In our time when the importance of scientific investigation is universally admitted and its necessity as a foundation for the evolution of preventive medicine is everywhere acknowledged, it seems strange that the essential etiology of smallpox should have been so long deferred. This becomes the more forcible when we consider that for over one hundred years the prevention of this disease has been firmly established through a preventive inoculation, while in other diseases the essential etiology of which has been well understood, such preventive inoculations have been wanting or have only been brought forward as the result of laborious scientific investigations. Beginning with the marked advancement of biology and the allied sciences which took place during the latter half of the last century research with respect to the causative agent of smallpox has not been wanting. These studies, until very recently, have been principally carried on in Europe and have led to no satisfactory result. All attempts to establish the disease as bacterial in nature having failed, the belief that it might be protozoon in character was advanced in certain quarters. To this end different observers announced the presence of certain bodies which were chiefly to be found in the epithelial cells of the cutaneous lesions and which, more or less, resembled various stages in the developmental cycle of protozoa. As might be expected, these views found vehement adversaries who denied the protozoon nature of these bodies and regarded them as various forms of cell degeneration, artifacts, etc. Up to the present time the matter has remained in this condition, neither side being able to produce facts which should finally affirm their contentions. After a review of the work which has hitherto been done along these lines it does not seem strange that no definite results have been obtained. Nearly all the work has been fragmentary and fails to deal with the problem in a comprehensive manner. Points which have been gained have not been followed up—thus their significance has been lost and the conclusions to be derived from them are wanting. About two years ago this problem was taken up anew by Professor Councilman and a chosen portion of his staff of the Department of Pathology of the Harvard Medical School. One year ago, at Washington, Professor Councilman gave a preliminary report of what had been accomplished. The work in its entirety is published in the February number of the *Journal of Medical Research*, and comment with respect to its significance is appended. Whatever views one may hold with respect to the correctness of Professor Councilman's conclusions, to the unbiased reader two facts are at once apparent: (1) This is by far the most comprehensive, thorough, and intelligent work which has as yet been done upon this subject. (2) Those who would contradict his assertions and receive credit therefor must do so as the result of studies which are as thorough, as comprehensive, and as intelligent as those of Professor Councilman. This at once disposes of all fragmentary and isolated work, and places his conclusions on a basis where they must be accepted until such investigations as mentioned shall have disproved their validity.

It is shown that in the early stages of the specific lesions of the skin and mucous membranes in smallpox, bodies are found which vary in form, structure, and size. They occur in the cytoplasm of epithelial cells, in the nuclei of such cells and free. The forms within the nucleus are subsequent to those which develop in the cytoplasm. They are present in the greatest numbers in cases of the greatest severity and rapidity of course. These bodies do not occur as isolated structures, but one form follows the other by gradual transmissions, forming a cycle which corresponds to the cycle of development of protozoa. In the different cases the same forms are found at the same period of the disease. The same forms are found in corresponding situations in the lesions in different cases. Bodies similar to these may be found in other diseases. In such, however, they show no sequence representing growth development and no complexity of structure. In vaccinia similar bodies are found, but here they are never present in the cell nucleus. The development of these bodies bears a definite relation to the symptomatology of the disease. These bodies must be regarded as protozoa. Otherwise it must be assumed that they are degenerations of a specific character, occurring under no other conditions, and that the products of degeneration undergo a development similar to that of a living thing.

In other portions of the work the supposed developmental cycle of these protozoa is traced with more or less success. Also the consideration of the conjugating forms which are supposed to appear only in the cell nucleus. The inoculation of these bodies into various animals and their presence in the lesions produced, has also been accomplished.

To our mind the vital features of this work are: (1) The demonstration of the presence of these bodies in the epithelial cells in all cases of smallpox examined. (2) The development of the forms which stands in direct relation to the clinical picture of the disease. (3) The inoculation of animals and the reproduction of the bodies in the epithelial cells of the inoculated animal. (4) The presence of similar bodies in the epithelial cells of the specific lesions of vaccinia. (5) The absence of the bodies in other diseases. If these points are admitted they negative the thought that these bodies can be artifacto —every competent person knows that any such regular appearance of artifacto could never take place. They also negative the thought that they represent the products of a specific cytoplasmic degeneration —for if they do, then the essential *initial* lesion of smallpox is a specific degeneration of the epithelial cell. Now, we know of no process leading to an immunity in which the initial lesion is a specific

degeneration of a single isolated body structure. Smallpox, however, is a disease conferring a high degree of immunity. Perhaps the nearest approach to a process producing a specific degeneration and leading to an immunity, is the cheesy degeneration produced by the bacillus tuberculosis—but there the conditions are very different—in the first place, cheesy degeneration is not an *initial* effect of the bacillus tuberculosis; in the second place, cheesy degeneration does not effect any one isolated body structure, as the epithelial cell, but various body structures. It seems certain, therefore, that on the basis of these statements the bodies described must be regarded as protozoa, and in our present knowledge as the causative agents of variola. For many years the causative relation of the malarial plasmodium to malaria was universally accepted on a no stronger foundation than this. Some may think that before Professor Councilman's views can be accepted the complete developmental cycle of the organism must be accurately demonstrated. This however, is far from being the true conception. It is no more necessary that this be done than it was that the conjugation of the malarial plasmodium in the intestine of the mosquito should be proven before it could be accepted as the causative agent of malaria. We believe, therefore, that the acts advanced by Professor Councilman, unless they are subsequently negatived, are sufficient for the opinion that these bodies are the chief causative agents of variola.

MIXED TUMORS OF THE SALIVARY GLANDS.

As the result of a clinical and pathological study, in conjunction with an analysis of the literature, Dr. Francis Carter Wood (*Annals of Surgery*, January and February, 1904) formulates the conclusion that there is a group of extremely complicated tumors occurring in the facial region and containing elements from both epiblast and mesoblast in most intimate relation with each other. The complicated structure of the stroma, containing as it does elements such as embryonal connective tissues, cartilage, bone, fat and lymphoid tissue, and rarely striated muscle, is explained most easily by the assumption of an embryonal misplacement of mesoblast. The structure of the parenchyma is so slightly characteristic in morphology that its epithelial nature in all cases can be considered only as probable; yet in about 24 per cent. of the tumors examined the presence of epithelium is undoubted. The form and relationships of the cells of the parenchyma do not furnish sufficient data to justify the conclusion that these cells are of endothelial origin. The theory of the early embryonal displacement of epiblastic tissue during the process of formation of the parotid and submaxillary glands and the branchial arches may account for many of the morphological peculiarities of the cells of these tumors, especially the lack of many typical features that are associated with epithelium. The same condition may be observed in the epithelial cells of the congenital moles, in which the epithelium is with difficulty distinguished from connective-tissue cells, owing to its close connection with the stroma of the tumors, and its undifferentiated type. The mixed tumors of the salivary glands pursue a clinical course strikingly different from that of the sarcomata and carcinomata in that they grow slowly and are generally benign. The regional lymph nodes are not invaded, and recurrences are likely to remain local in a considerable proportion of the cases.

IS THE GENERAL PRACTITIONER PASSING AWAY?

When we published an account of the work of good Dr. Rial Strickland, the typical general practitioner of the old school, who had worked in willing harness for sixty years, we were quite sure that his example would touch a sympathetic chord in the hearts of many readers. Even in these days of progressive specialism and the necessarily multiplied division of labor, it is pleasant to be assured that the all-round family physician still holds his own and is not yet ready to be relegated to the rear. It would be a pity if it were otherwise, when we consider the many and varied necessities of his existence, as the general adviser and old-time friend of the families that make his large and responsive clientage. In many communities he is still the court of appeal in every emergency of sickness, and is the first to be called in case of accident. His functions in this respect have survived all arguments against his general fitness for their dutiful and skilful discharge. It is comforting also to realize that under the circumstances of his existence he is not altogether the man who is especially dangerous to be allowed to go at large and dispense disinterested advice to such of his numerous patients who place absolute trust in his common-sense judgment. The time has gone by when he needs to officiate as clergyman or undertaker in chance cases, or perhaps draw a will for some unfortunate who may have no other friend, but he still retains many of his time-honored privileges, which few of his patrons would willingly have him relinquish. He is, in fact, the man who must never run when real trouble is to be faced. Nor does he. He must be as ready to perform podalic version, cut loose a strangulated hernia, or give air to a choked windpipe as to right his overturned sleigh, splice his trace or lead his plunging horse through a midnight snowdrift. He must be naturally self-reliant, and indoors and out, by bedside and on highway therein is the constant stimulus for its exercise. It is well that it is so, for he needs the training that fits him for his many and varied duties.

To his credit also be it said, he has learned by long and often painful experience the limit of his talents. In such respects he may be an example for his more pretentiously expert brother, who is constantly striving after impossibilities and risking the application of every new fad to the supposed needs of his trusting victims. He may be a trifle slow in adopting new ideas, but what he loses in one direction he may gain in another. Even here he is safe in being reasonably conservative. The curable diseases are as safe in his hands as in those of the most noted experts, and as for the incurable maladies, the time element, perhaps, is the only one that appeals alike to the small and large fee man. One perhaps may appear to do more than the other, but the general result is quite sure to equal the ordinary statistical level of a general and well-regulated mortality. Thus what is really necessary for actually preserving and prolonging life is as much within the reach of the ordinary working private as with that of his presumably ranking confrère.

It is scarcely fair either to tax the general worker with want of zeal or lack of capacity in meeting the exigencies of his situation. The active competition in his own ranks is a sufficient stimulus for progressive effort in required directions. Improved methods in diagnosis appeal to him in more direct and practical ways perhaps than to the more assertive and complacently confident expert. In applying them to his own needs he makes good use of the conclusions of those who have spent the time and labor in solving the difficult problems of disease causation. While research work may establish principles, the practitioner is able to apply them in the purely clinical way that must make him the successful therapeutist. His mission is to cure disease in the direct and convincing way at the actual bedside of the patient. He is pure and simple the practical clinician who must either make good his prognosis or acknowledge his incompetency as a trusted medical adviser. The microscope and test-tube are always at hand to confirm his conclusions in a sufficiently demonstrative way for his purposes and make him sure of his course.

Thus with the majority of ordinary ailments he is as much an expert as the one who within narrower limits makes equally laudable efforts at precision of judgment. It is admittedly incumbent upon him when no expert help is at hand to be prepared to meet all extra ordinary emergencies. Fortunately these are comparatively infrequent, and when they do occur they can be amenable to ordinary skill, but if not, there is usually abundant time to send for assistance, without very great risk to the patient. Doubtless, on the other hand, the self-reliant and conservative physician is often surprised at the number of apparently desperate cases that eventually recover by the simplest forms of treatment. Thus the experience of the active general practitioner, and particularly that of the country doctor in lone districts, makes the purely medical adviser not only a broad man but a safe one. While the specialists divide the body into rapidly multiplying restrictive regions, the general practitioner unites them in a harmonious constituency, maintains rational autonomy, regulates mutual dependencies, maintains coördination of functions, manures the root and reaches the fruit by nature's simple and long-approved methods. In spite, then, of cries to the contrary, there is still left enough work for him to do, and it is high time that he should be allowed to present his side of the argument.

The Home in Its Relation to the Tuberculosis Problem.

Of recent years there has been a great deal of glib talk as to the comparative ease of extirpating tuberculosis. Article upon article have been written, all to the effect that if only rational methods were followed that consumption would, in the course of time, be, if not an almost extinct disease, at least so greatly lessened in scope and virulence that, as a factor in the mortality statistics, it would be, to all intents and purposes, a negligible quantity. The difficulty lies in the fact that many of the measures recommended are nearly impossible to put into practice. The rich and well-to-do are able to treat the disease as it should be treated, but with the poor the situation is very different. This latter class cannot live under conditions calculated to stay the progress of the disease. A very large proportion of the working population of all countries are compelled to live huddled together in a most unhealthy manner, and are unable to procure suitable food, the consequence being that the victims of tuberculosis become worse, and spread the malady among their family and neighbors. Only a small number of these can be sent away to the country to be properly treated, while the majority must remain in their homes to act as foci for the dissemination of disease germs. Thus, if consumption is to be banished, means must be devised to improve the dwellings of the poor and to effectively treat the indigent consumptives in their homes.

Dr. Osler, in a lecture delivered a short time ago, under the auspices of the Phipps Institute, Philadelphia, discussed this phase of the tuberculosis problem. In his opinion, the measures to be adopted to render home treatment of the consumptive poor efficacious should be on the lines of a sanitary campaign. First, by an educational campaign in the homes. To carry this out efficiently there should be, secondly, in all cities a compulsory notification of cases. Thirdly, in most cities the powers of the health boards should be greatly enlarged, so as to deal efficiently with the question of proper disinfection of the houses occupied by tuberculous patients. Fourthly, the question of the housing of the poor needs attention, particularly in the matter of proper control of tenements, and the regulation, by law, of the number of persons in each house. Fifthly, by placing upon the landlord the responsibility of providing, under the control of the Board of Health, a clean, wholesome house for a new tenant. Sixthly, the wholesale condemnation of insanitary streets and blocks, and the rebuilding by the municipality, as has been done in Glasgow and elsewhere.

Dr. Osler states that the following two points should be strongly impressed upon general practitioners. First, that early recognition of the disease can only come from better methods of practice, and greater attention to the art of diagnosis. The second point is the necessity for a more masterful management of the early cases. The lecturer expressed his firm conviction that more tuberculous patients are injured than helped by drugs.

According to Dr. Osler, these are the essentials in home treatment of tuberculosis in the small towns, and country places and suburbs of our large cities: (1) To gain the confidence of the patient, since confidence breeds hope; (2) a masterful management on the part of the doctor; (3) persistence—benefit is usually a matter of months complete arrest a matter of years; absolute cure a matter of many years; (4) sunshine by day, fresh air by night and day; (5) rest while there is fever; (6) breadstuffs and milk, meat and eggs.

The first, and by far the most important, step in the attempt to drive away consumption is to improve the conditions of life of the poor. If this be not done, tuberculosis will not be checked to any extent. The insanitary, overcrowded buildings in which swarm the poor, in all the large cities of the old and new world, must be torn down, and well-lighted, well-ventilated, and commodious buildings must be erected in their stead. All other methods of combating the disease but touch the fringe of the evil.

The main point is to render the dwellings of the poor healthy; so long as the homes themselves are unhealthy, it is useless to talk about home treatment. Glasgow and some other British cities have set a good example in this respect, and have shown that even municipalities may have consciences. It is time that New York, Chicago, and the large American cities generally should recognize their responsibilities.

Common Sense and Radium.

The real properties and the alleged properties of radium would seem to have overturned the rational reasoning faculties of a large portion of the American public and of some of the medical men. Statements for which there is no foundation whatever are being constantly advanced as to the marvelous events that can and will be brought about through the influence of radium. A French scientist has affirmed recently that the heat rays of radium are capable of melting stones, and of disintegrating, with great celerity, iron and steel, so that the effects of the exceeding heat of its rays will destroy fortifications, crumble battleships, and will extinguish human life like dew before the morning sun, thus rendering warfare impossible. In pseudo-scientific articles and in medical literature, to a certain extent, the most extravagant claims have been made for radium. The *New York Times*, May 8, contains an article by A. Frederick Collins, in which cold water is thrown upon some of the far-fetched assertions made by too enthusiastic or unscrupulous advocates of radium. Commenting on radium in the treatment of cancer, the writer says "that radium cannot begin to compete with ultra-violet light in its healing properties, and even ultra-violet radiations are not positive and absolute in every case by any means. There are no diseases known to the medical profession for which the *x*-rays or ultra-violet radiations are not superior in doing the work better and quicker than radium." It must be understood that the scarcity of radium is an almost insurmountable obstacle to physicians who wish to use it. A grain of radium having a radio-activity of 20,000, costs $1,250. Consequently, few physicians possess the subtsance of this activity, but have to use that having an activity of 1,000, 3,000, or 7,000, and which has so comparatively a slight effect upon malignant growths, that treatment by such means would take too long to warrant its use. As has been said on several occasions in the Medical Record, the properties of radium have not yet been sufficiently tested. It may fulfil all the predictions which its ardent supporters have made as to its curative and other properties, but in the meantime it is useless and harmful to unduly exalt its influence.

The Curability of Leprosy.

The report, published in many of the lay papers of the United States, that Dr. Dyer of New Orleans had advanced a statement concerning the curability of leprosy, was received with skepticism by those who had made a study of the disease. Dr. Dyer is said to have declared that not only was leprosy curable, but that he had himself eradicated the malady. The remedies used by him were potassium chlorate and chaulmoogra oil.

Dr. Albert S. Ashmead of New York contributed to the *New York Evening Post* a letter in which he sharply criticized Dr. Dyer's alleged statement. He points out that in the first instance the two years which have elapsed since the last report was made to the Legislature of Louisiana by those having charge of the Leper Home, is far too short a time for anyone to judge that a case of leprosy had been cured. Attention is also drawn to the fact that potassium chlorate and chaulmoogra oil have been used in all places in which leprosy exists for a considerable period, and asks why, if perfect success could be obtained in Louisiana, should it not be obtained elsewhere.

The chaulmoogra oil treatment of leprosy, according to Dr. Ashmead, was instituted a thousand years ago in India and East Asia. Tourtoules Bey, a leprologist of Cairo, Egypt, who made use of it by hypodermic injections of five-gram doses, obtained regressions, which after five hundred and eighty-six injections, lasted five and six years. But even, when this long period of apparent cure had expired, he "hesitated to say" that he had secured cures by its use. On the contrary, he expressed his belief that they were not materially benefited. The chlorate of potash treatment has been widely tested in leprosy cases, but has not had the favorable effects claimed for it by its advocates. The serum treatment of leprosy has also had but litt e success.

Dr. Hansen, the discoverer of the bacillus of leprosy, believes that the vegetable bacillary organism of the disease has a spore life, which is wholly unknown to us. In a letter to Dr. Ashmead he says: "Though we cannot cure leprosy, we can prevent it by isolation of our patients. Until we succeed in cultivating the leper bacillus—that is, developing colonies of bacilli outside of human flesh—we shall try in vain for a healing serum."

At the present time our knowledge of the etiology of leprosy is not sufficiently definite to warrant the statement that a cure has been found. At any rate the reported cures at the Louisiana Leper Home must stand the test of a much longer period of time than is now the case before it will be believed that a curative treatment of leprosy is possible.

Relation of Inebriety to Mental Disease.

Dr. Robert Jones, Medical Superintendent of the London County Council Asylum at Claybury, recently read a paper on the above subject. Alienists all agree that alcoholism tends to bring on insanity, but as to whether the habit is a fertile source of mental disease is a point upon which agreement has not been reached. Some contend that drinking to excess is responsible for a large proportion of the cases of insanity which occur with apparently increasing frequency in civilized lands, while others declare that the harmfulness of taking an undue amount of stimulating drinks, so far as the production of mental disorders is concerned, has been greatly exaggerated. Dr. Jones takes the more pessimistic view of the matter, and attributes to drink a substantial percentage of the insanity in England and Wales.

In the paper which he read, he first discussed the chemical compositions of the various alcoholics, and then described the mental effects produced by ordinary alcohol, according to the quantity ingested, and said that a tendency to the development of illusions of a visual character and to delusions of a persecutory nature was characteristic of the effects of alcohol, as was also the tendency to sudden impulsive movements. Dr. Jones divided the class of inebriates into two divisions, the periodic drinker and the more or less constant drinker. The victims of these two classes were of different ages, those in the periodic class being mostly young men who, in the intervals of their paroxysms, were apparently rational and fulfilled their obligations both to society and to their friends. There doubtless was in all inebriates a considerable mental deterioration, as was evidenced by the fact that over 20 per cent. of all the inebriates under treatment in retreats and reformatories in Great Britain were transferred during one year, 1902, into asylums for the insane. The author then gave statistics dealing with the effects of alcohol. He stated that out of the 116,000 insane patients at the present time detained in English asylums there were probably no less than 11,000 males and 6,000 females whose insanity was directly or

indirectly caused by drink. He quoted the statistics of the London County Asylums for the ten years 1893-1902, inclusive, and stated that during this period 35,916 persons had been admitted into these institutions, of whom a proportion of 21 per cent. among the men and 11 per cent. among the women were ascertained to owe their insanity to drink alone. To Claybury Asylum there had been admitted during the period, 1893-1902, inclusive, 9,544 persons, of whom 1,664 owed their insanity to drink, a proportion of 22.7 per cent. among the males and 13.1 per cent. among the females. He stated that there were 400 persons at the present time in retreats and reformatories whose detention was caused through inebriety, and that this only represented a small proportion of the inebriates in the country whose presence among the young was most injurious, both directly through their neglect and cruelty toward those for whom they were responsible, and indirectly by their evil influence and example. Dr. Jones said that "his experience of the treatment of 'drink cases' in asylums had been a disappointing one, as to the actual recovery which took place, for when such patients were discharged they almost invariably relapsed if they tasted alcohol at all, and they were only a few who could afterward go through life without it."

Habitual Constipation.

In these days habitual constipation, and especially among Americans, is so common a complaint and occasions so much distress and even disease, that remedies to relieve the condition are always welcome. Sir James Sawyer of Birmingham, England, a short time ago delivered a lecture on the subject which contained a great deal of common sense advice pointing to the relief of the trouble. The writer thus defines the condition: Constipation is slow fecal progress in the large intestine, where alone true fæces are to be found." With regard to treatment Sawyer lays down the following rules: (1) We should never leave the medicinal treatment of constipation of the bowels to our patients. (2) We should never give drugs in the treatment of habitual constipation until we find that the constipation cannot be cured without them. (3) We should never give drugs in the treatment of habitual constipation without the conjoined use of a well-selected and judicious combination of the numerous adjuvants of natural alvine relief which are at our disposal. The causes of habitual constipation are, according to the writer, largely due to a habitual abstinence from emptying the rectum whenever the physiological urgency to empty it is felt; it is also due to habitual defecation when seated upon a high seat; it is also due to habitually diminished activity of the abdominal and respiratory muscles; and it is also due to habitual abstinence from fruit. A healthy person, by education, should empty the rectum daily, so that defecation becomes, to a certain extent, a regular rhythmical process, occurring at a fixed time, once in each twenty-for hours. Referring to the prevalence of habitual constipation amongst women, Sawyer is of the opinion that the causes of this are to be found in irregularity as to the time of effort of defecation, in the putting off the act, in relative feebleness of the abdominal muscles, in the wearing of waist belts, and in the wearing of "stays" and corsets. The diet recommended by the writer in the treatment of habitual constipation is a mixed one, and if the condition does not yield to such means, articles of food which are found to have a laxative tendency when ingested should be added to the dietary, or increased therein. Such laxative foods are found in green vegetables, in fruits, in fruit jams, and especially in orange marmalade and in honey. Sawyer's favorite drug, when drugs are found to be absolutely necessary in the treatment of habitual constipation, is aloes. He has little faith in belladonna or in nux vomica.

News of the Week.

Medical Substitutes for House Staffs of Bellevue and Allied Hospitals.—Graduates in medicine who desire to substitute for members of the house staffs of Bellevue, Gouverneur, Harlem, and Fordham hospitals, absent on leave, may apply with credentials giving time and place of graduation, hospital experience and references, to the superintendent of Bellevue Hospital, First avenue and East Twenty-sixth street.

Dr. William B. Pritchard has been appointed visiting neurologist to the City Hospital, New York.

Suit for Typhoid Damage.—An association has been formed in Butler, Pa., to bring actions for damages against the water company, the damage having been caused by the typhoid epidemic which lately ravaged that town, and the allegation of the complainants being that it was the result of negligence on the part of the water company in failing to protect the sources of its water supply and to maintain the purity and potability of the water it distributed.—*New York Times.*

The Prosecution of Alleged Illegal Practitioners of Medicine.—Thomas E. Eldridge, head of the Electrotherapeutic Institute of Philadelphia, was recently held in bail for court by a magistrate on the charge of practising medicine without a license, and also on a second charge of obtaining money under false pretenses from a patient under his care.

Clinton L. Shoemaker, a druggist of Philadelphia, has been arrested on the charge of practising medicine without a license. He is said to have attended patients and to have accepted fees in payment or his services.

Cerebral Localization.—Prof. Charles S. Sherrington, M.D., LL.D., F.R.S., of the University of Liverpool, delivered a lecture on "Cerebral Localization" in the medical hall of the University of Pennsylvania on May 5. He related the results of observations made upon chimpanzees and orang-outangs to determine the motor areas for the various parts of the body. The skull was opened and the faradic current was applied in different situations and the motor responses in the several parts of the body noted. It was found that the motor area in these animals was confined largely to the precentral convolution, the post-central convolution being apparently silent. Similar conclusions were reached also as a result of ablation-experiments. An area controlling conjugate movement of the eyes is present in the frontal lobe and another for ocular movements in the occipital lobe. The complexity of the sulci and the convolutions in the higher apes closely approach that in man.

Philadelphia Hospital Deficits.—As a result of the large increase in the cost of foodstuffs, together with increased demands on their facilities, fuel, cotton, and other supplies, the hospitals of Philadelphia—and probably of other cities as well—are confronted with deficits of varying degrees of magnitude. Some of these institutions receive State aid, while a number do not. The deficit for the year incurred by the Pennsylvania Hospital is $33,692.90. At the Hospital of the University of Pennsylvania, where the expenditures reached $200,000, the deficit was $30,000. The Presbyterian Hospital, which spent about $137,000, had a deficit of $16,000. The deficit

at the German Hospital was $12,000; at the Jewish Hospital between $10,000 and $12,000; and at the Hahnemann Hospital about $20,000.

St. John's Guild.—St. John's Guild has sent out its annual appeal for funds with which to carry on its work in the relief of sick children by the guild's floating and seaside hospitals. The appeal points out that 25 cents will give one baby one trip on the floating hospital. Fifty cents will pay for the baby's mother, and the contribution of $1 will afford a day's enjoyment on the water for a family. The medical, nursing, and food expenses of one baby at the seaside hospital for one week are $5; $10 will do the same for the child and its mother; $50 will name a bed for one month on the floating hospital; $250 will name a trip on the floating hospital, and $500 will name in perpetuity a crib on the floating hospital or at the seaside hospital. Membership dues are $10 per annum.

Foreign Appointments for Members of the Medical Faculty of the University of Pennsylvania.—Dr. Mazyck P. Ravenel and Dr. Leonard Pearson of the University of Pennsylvania have been chosen to make special research in the Maragliano laboratories of Genoa, Italy, for the prevention and cure of tuberculosis. Dr. Maragliano is professor in ordinary to the Royal University and an Italian Senator, and has selected Drs. Ravenel and Pearson to make the investigations. They will sail for Italy in a short time.

Clinical Professor of Genitourinary Diseases in Columbia University.—The trustees of Columbia University have appointed James R. Hayden, M.D., clinical professor of genitourinary diseases, in succession to Dr. Robert W. Taylor, and have also appointed Dr. Arnold H. Knapp, clinical professor of ophthalmology.

Physicians' Building on Madison Avenue, New York.—The old Madison Avenue Hotel, which has been reconstructed, was opened on May 2 as a building to be devoted exclusively to the use of physicians. The building contains fifty-five suites of offices. The most stringent regulations have been adopted with regard to tenants. Only physicians of unquestionable standing can gain admittance. All applicants for offices must be passed upon by a committee composed of lessees of suites. This committee at present consists of Drs. George H. Fox, Freeman F. Ward, Daniel Lewis, Wm. B. De Garmo, and Robert T. Morris. No other profession nor commercial enterprise can secure tenancy in the building.

Jewish Charities Congress.—The National Conference for Jewish Charities will hold its third biennial meeting from May 24 to May 27 in this city

Tuberculosis among the Street Cleaners of New York.—The medical examiners of the Street Cleaning Department have been instructed to make a physical examination of the five thousand sweepers and drivers employed by the city of New York. A large number of the men who have asked for sick leave recently were found to be suffering from pulmonary tuberculosis, and Commissioner Woodbury wishes to know to how great an extent his force is infected.

Hospital on Immigrants' New Ferry Boat.—The new ferry boat, *Ellis Island*, which will be used for the transport of immigrants, has just begun her duties. The boat is 160 feet long and 45 feet wide, and has two decks, the lower being fitted for the accommodation of about 1,000 immigrants, while the upper is to be used by officials and passenger, from New York. A hospital with room for twelve beds is a feature of the boat, and there is also a padded cell for the reception of any violently insane immigrant.

A Paradox of the Death Rate of New York City.—The Tenth ward of New York city, which is the most densely populated district in the world, has a present population of about 72,000 in an area of 110 acres, or 655 persons to the acre. The Eighteenth ward has a population of 51,000 in an acre of 450 acres, or about 136 persons to the acre. By a recent weekly report of the Board of Health, the number of deaths in the Tenth ward was less than in the Eighteenth ward with its smaller population, and in a year there are 1,200 deaths on an average in the Tenth ward and 1,500 in the Eighteenth. The same rule of disparity prevails generally through the wards of New York, the actual death rate being least in those which are most thickly populated and largest in those less thickly inhabited. The Seventh ward has a present population of 90,000, while the Twentieth ward uptown has likewise 90,000 inhabitants. By the Board of Health report for the third week of April, there were thirty deaths in the Seventh ward and sixty-three in the Twentieth. In a year there are 1,300 deaths in the Seventh ward and 2,000 in the Twentieth.

Epidemics at Mukden.—The following statement has recently been made by the Associated Press in regard to the reported epidemics at Mukden: "There are some cases of dysentery and smallpox and several cases of typhus in the Mukden hospitals, but there has been no application for more surgeons nor for special remedies or serum, and it is entirely misleading to say that epidemics exist. Smallpox and typhus are epidemic in Manchuria, and dysentery is inevitable where large bodies of men are crowded together."

Plan to Reorganize Red Cross Society.—A plan for the general reorganization of the American Red Cross Society has been submitted by Senator Proctor to representatives of the parties to the controversy in that organization which, if accepted, will reconcile the differences that now exist in the organization. The plan was drawn by ex-Secretary Foster at Senator Proctor's request, and contemplates the coöperation of the National Government in the work of organization. The plan consists in the issuance of a new charter by Congress, which shall vest the control of the affairs of the organization in a central governing body of eighteen persons. Of these, six are to be appointed by the President, who also is to designate the presiding officer. For the present the remaining twelve members are to be chosen by the General Association, the understanding being that both elements are to be represented. There is, however, a provision for subsidiary State associations, which after they are organized, are to be allowed to name six of the twelve members. There is a requirement for an annual report to Congress, and also for a yearly auditing account by the Treasury Department.

American Laryngological Association.—The twenty-sixth annual congress of the American Laryngological Association will be held at Hotel Chelsea, Atlantic City, N. J., June 2, 3, and 4, 1904. The profession is cordially invited to attend.

Pneumonia Mortality in Chicago.—The pneumonia mortality has already broken all April records. During the first twenty-three days of the month 403 deaths were reported—a daily average of 22. The April daily average for the previous fourteen years had been 12.4. For the current month the daily

deaths from pneumonia have been 78 per cent. higher than usual. The following are the figures for the cities of New York and Chicago during the present season, November 1, 1903, to April 23, 1904, inclusive—175 days:

	New York.	Chicago.
Total deaths, all causes	38,364	14,229
Deaths from consumption	4,299	1,498
Deaths from pneumonia	7,091	3,109
Proportion per cent. of all deaths—		
From consumption	11.2	10.5
From pneumonia	18.4	21.8

Europeans Die of Sleeping Sickness.— A young Congo official is reported to have died of sleeping sickness in the Antwerp Hospital on May 5.

Regulations in Regard to Milk in New York City.—Dr. Darlington, Health Commissioner of New York City, has sent out notices to all milkdealers and railroads in the city that all milk, the temperature of which is higher than 50°, will be seized and destroyed, and the offending persons prosecuted. The cause of the sanitary code directing such action has been unenforced hitherto.

Another Bellevue Physician Seriously Ill.—It is reported that Dr. Joseph F. McCarthy, 137 West Forty-third street, now a visiting physician, and up to eighteen months ago an ambulance surgeon at that institution, is dying of tuberculous meningitis at the hospital, where he contracted the disease several weeks ago.

Outbreak of Plague among Coolies in South Africa.—Plague has broken out among the Chinese collected at Kowloon for transporation to the Transvaal mines. The charters of steamships engaged to convey the coolies have consequently been cancelled.

Horse Disease in Iowa.—The investigation made by the Department of Agriculture of the horse malady which has broken out in Iowa has shown that the disease was brought to this country by horses imported from France. The malady, known as coit, is said to be caused by parasites.

Hospital Beds Endowed by Elks.—At the Ladies' Social Session, held on the evening of May 5, at Elks' Hall, Dr. D. B. St. John Roosa, president of the Post-Graduate Hospital, accepted two beds for that institution proffered by the society. Champe S. Andrews, Exalted Ruler of the New York Lodge, in his presentation of the two beds, said that since 1868 the mother lodge of Elks had dispensed in volunteer charity nearly $250,000.

Obituary Notes.—Dr. WILLIAM BARTON HOPKINS died of cholera morbus in Philadelphia on May 4. He was a grandson of Dr. Samuel Hopkins and a grand nephew of Dr. John Rhea Barton. He was surgeon to the Pennsylvania Hospital and to the Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases, and he had been for many years surgeon to the Episcopal Hospital.

Dr. ORISSA W. GOULD, well known for her philanthropy and missionary work, died on May 3 of cerebrospinal fever at the New York Hospital. Dr. Gould was forty-three years old. She began the study of medicine at an early age, and was graduated from the Women's Medical College of New York in 1892. Her father was a Baptist clergyman.

Dr. CLINTON CUSHING, one of the oldest and best known physicians of Washington, died suddenly at his home there on May 10. Dr. Cushing retired from practice some years ago.

Dr. GILES S. MITCHELL, one of the best-known physicians in Cincinnati, died suddenly at his home in Avondale on May 5. He was fifty-two years old, was born in Martinsville, Ind., and graduated from the Medical College of Ohio in 1875. He was a professor of the Cincinnati College of Medicine for a number of years and president of the Academy of Medicine in 1881.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HOSPITALS, FINANCES AND MANAGEMENT—MEDICAL DEFENCE—PEPTIC ULCER OF JEJUNUM—CARCINOMA OF THE RECTUM—THE LATE SIR HENRY THOMPSON, DR. SAMUEL SMILES, AND COL. CHESNAYE.

LONDON, April 22, 1904.

GUY'S HOSPITAL is issuing its annual report—a document which affords food for reflection. It contains, of course, the usual outcry for more money. Last year the governors expressed an anticipation that the public would come to their assistance in consequence of their efforts to place the hospital in the forefront of efficiency and usefulness. Now they have to report that they are disappointed, and therefore the burden of debt has increased. At the present time £77,000 is wanted for the discharge of existing liabilities on account of renovations and buildings which are simply called indispensable, but which some critics may perhaps pronounce extravagant or even reckless. I am half afraid the managers of Guy's are as much obsessed as other hospital authorities with the notion that a heavy debt constitutes the most effective appeal to the public. The settled income of the hospital is stated as at least £15,000 per annum below its ordinary requirements—a fact which should render the governors extremely cautious about incurring further liabilities for buildings and renovations.

The report boasts that, for the first time since 1884, all the wards came into use during the past year—a fact which some might consider as proving that for twenty years unnecessary buildings have been kept up. The in-patients admitted in the year numbered 8,191 and the out-patients the striking (some might say, the scandalous) total of 128,051. No wonder we are told that the financial support received altogether failed to meet the requirements. The boast that these figures exceed those of any previous year of the hospital's long existence, may well give fresh impetus to the cry for hospital reform, and especially to the arguments of those who maintain that the out-patient departments are actually pauperizing institutions.

Another hospital, on a smaller scale, demands notice in this connection, inasmuch as it has been rebuilding since 1902, and yesterday the out-patient department, being the first section completed, was thrown open. This institution is the Royal Waterloo Hospital for Children and Women, founded in 1816 and which confessedly stood in need of renovation. The scheme for rebuilding it entirely at a cost of £50,000 was adopted, as I have said, in 1902, and £15,000 has been expended on the portion now ready. But toward the fund only £20,000 has been contributed, and the governors are now afraid that they may not be able to carry out the remaining sections. In that case the provision for the in-patients would have to wait. It was intended to have two hundred beds, but the less important department has been given preference—perhaps as it will enable the managers to put in their appeal the large number of patients relieved. Soon, let us hope, the public will learn the little importance of the out compared with the in-department and cease to be caught by the bait of large numbers.

What is likely to happen in some of our overcrowded out-patient departments is alleged to have occurred at the Bolingbroke Hospital—a useful suburban institution as far as in-patients are concerned. At an inquest on a child that died from pneumonia after severe burns, the mother declared the child had only been seen by a nurse and was refused admission for want of room. If no bed could be utilized in the hospital, a medical man seeing the child would probably have recommended application to another institution rather than attendance as an out-patient. I must add that the chairman has since written to the papers to say a doctor did see the child. It seems strange that no witness appeared to say so at the inquest.

There is another danger of the overcrowding of the out-patients. Many are kept waiting for two, three, or four hours, or even more, to take their turn to see the doctor. Many children are thus waiting, and now and again a patient is among the crowd with measles, diphtheria, or other infectious disease which is thus easily spread. Besides what a terrible trial it is for some poor sufferer to be thus kept waiting to see the doctor. I know of a case in which a woman waited last week for four hours and then the doctor left without finishing his work. No doubt she will be counted among the "relieved."

Medical Defence still occupies some attention. The British Medical Association having referred it to the branches some of them are circularizing their members and asking for an answer—yes or no—if they support the scheme and if they will join and pay the extra subscrip-

tion. As this amount is fixed as the same as that of the two existing defence societies, it is difficult to see what advantage can come from the absorption of their machinery by the bigger organization. Unless some distinct advantage can be shown, the Defence Union may well refuse, while the London and Counties' Society may as reasonably decline the British blandishments.

The attitude of the profession to the subject is unfortunately one of apathy. Otherwise the protection societies would number the majority of qualified men in their ranks. This is far from the case, and even the British has not enrolled more than about half. Its scheme too, seems excessively complicated and offers none of its funds for the work of the new department. The two defence societies have done very well so far, and every one to whom I have spoken on the subject seems to think the best thing would be for these two to unite their forces and carry on the work in which their experience is a valuable asset.

Mr. Mayo Robson reported to the Medico-Chirurgical Society a case of peptic ulcer of the jejunum—the first, so far as he could ascertain, recorded in England. Altogether fifteen cases have been recorded, all occurring after gastroenterostomy, nearly all after the anterior operation, all after perforation had taken place. He then gave some statistics about peptic ulcers. Out of one hundred and twenty-eight posterior gastroenterostomies which he had performed there had not been one instance of jejunal ulceration. But out of twenty-nine anterior operations there had been the one now reported. It occurred three years and four months after the anterior operation which was performed for pyloric and duodenal ulcer, the patient having been well during two years of the interval. He excised the jejunal ulcer and did a Roux's operation, this patient made a good recovery and is now quite well. In reply to questions, Mr. Robson expressed the opinions that the greater liability to the lesion after the anterior operation is due to defective drainage of the stomach with consequent persisting hyperchlorhydria; that the closure of the pylorus was due to cicatrization, not to loss of function, and that the adhesions were due to perigastric inflammation and often prevented peritonitis when perforation took place; he had often seen adhesions round a perforated gastric ulcer.

Dr. H. J. Cotton submitted to the Medico-Chirurgical Society quite a little catechism on a case which he related of ulceration of the rectum, diagnosed two years previously as cancer, when patient refused colotomy and continued to work with the help of morphine and cocaine suppositories. At length high fever, burrowing of pus and fæces led to ischiorectal abscess, which was excised. Admitted to Guy's Hospital, March, 1903, in a desperate state; colotomy was done, though the microscopical report was "columnar-celled carcinoma." Steady recovery followed; in six weeks he left hospital and resumed work. He has now regained his usual weight, though there is still occasional discharge of blood and much from the anus, but the intolerable pain has gone. Here is Dr. Cotton's cathechism: (1) What was the man's complaint? (2) Is not the fact that he recovered from the blood poisoning of burrowing pus and fæces and has regained his weight and enjoyed ten months' good health inconsistent with cancer of three years' standing? (3) Does not true cancer live on its host, producing emaciation and cachexia in which the operation would be fatal? (4) Was the microscope, or rather the microscopist, at fault as columnar cells are natural to intestinal epithelium? (5) Is it wise to apply the word cancer to diseases of low malignancy which may last for years? In the discussion that followed, the president (Sir D. Powell) said he had seen cases with a long period of quiescence after colotomy. Mr. Robson said that if inflammation was added to carcinoma of the rectum a great accession of symptoms was provoked, but much relief occurred if the inflammation could be reduced. He referred to a case which lasted five years, and urged early operation when the growth is limited, but if too late for that, colotomy. He spoke of some undoubted cases of sarcoma in which the growth quite disappeared after colotomy. Mr. Paterson mentioned a case of colotomy for carcinoma in which he saw the patient three and one-half years afterward in good health. Mr. Wallis said he had examined Dr. Cotton's patient and had no doubt that it was a case of carcinoma. He said tubercle sometimes resembled a cancerous growth. Mr. Armour also referred to a case of long quiescence after colotomy.

Sir Henry Thompson died on Monday afternoon, in his eighty-fourth year, after only a few days' illness. By this event the profession loses a most interesting personality as well as a surgeon whose reputation is too well known to you to need reference. He took the M.B. London, 1851, and the next year the Jacksonian prize of the Royal College of Surgeons on "Stricture of the Urethra," thus early, as it were, adopting the specialty which he has followed with such distinction. The next year he took the F.R.C.S. In 1856 he was appointed assistant surgeon to University College Hospital, and followed with energy the specialty, and in 1860 won a second Jacksonian prize, the subject for that year being the "Healthy and Morbid Anatomy of the Prostate." He became full surgeon to his hospital in 1862, but continued to see outpatients for ten years longer. He resigned and was made consulting surgeon in 1877. Thompson was in some degree a pupil of Civiale, for with the energy which characterized all his doings, he went to Paris to study the great lithotritists' work, whose methods he afterward followed. You will remember the case of King Leopold I, who had been operated on by Civiale. Later Thompson removed one or two fragments which gave trouble. He then wrote to Civiale that the King's cure had been completed by his grateful pupil, by the art he had taken such pains to teach him—an acknowledgment which Civiale greatly appreciated. In 1867 Thompson was knighted. (How well I remember the occasion.) He was created a baronet in 1899. You need not be told how quick he was to do justice to Bigelow. Indeed nothing connected with his specialty escaped his attention, and so thoroughly did he keep up with surgical and scientific progress that it sometimes seemed wonderful, how he also kept abreast with so many social, political, literary, and artistic matters. He was a pioneer in the revival of cremation here. He was a painter of considerable ability, exhibited often at the Academy, at one time studied with his usual energy under Alma Tedama. Sir Henry was also a collector of china, and in conjunction with Whistler published an illustrated catalogue. At one time he had an observatory and was always interested in astronomy. He wrote a couple of novels which had a certain success. He was much interested in the temperance movement and a powerful advocate of moderation in diet—though the dinners for which he was noted were of the most recherché kind and at them he had entertained most of the leading writers and thinkers of the day.

Dr. Samuel Smiles died on Saturday in his ninety-second year. It is so long since he left medicine for literature that you may perhaps have forgotten that he took his M.D. at Edinburgh University, where he began to practise, but soon after removed to Leeds. In 1837, he finally abandoned medicine and succeeded his friend, Robert Nicholl, the poet, as editor of the *Leeds Times*. The next year he produced a work on "Physical Education; or the Nurture and Management of Children," which contained the result of his medical experience on the subject. In Leeds he became acquainted with George Stephenson, the railway pioneer, whose life he published in 1857. This was an instant success, and ran into five editions within a year. Prior to this he had been intimately associated with railway enterprise as secretary to the North Eastern and afterward to the South Eastern Company. He had also published a book on "Railway Property," 1849.

It was not until 1859 that his book on "Self Help" appeared. At once that work attracted great attention and established his position as a writer to be reckoned with. Between this date and 1887 he produced the four other books which make up the five volumes of the "Self Help" series. Besides these he also wrote a number of biographical volumes, the last of which, on Josiah Wedgwood, appeared in 1894 when he was eighty-two years old. "Self Help" has been translated into seventeen languages. In 1878 his university recognized his position by awarding him the honorary LL.D., and various other distinctions fell to his lot before his complete retirement from active work, including two or three foreign orders.

Col. Geo. Cochêt Chesnaye, F.R.C.S.I., died last week aged sixty-seven. Educated in Dublin, he qualified in 1857–8, taking the Carmichael prize in surgery. He entered the Indian Medical service in 1859, was in the Hazara campaign, the Loostian expedition, the Afghan War, etc., being mentioned again and again in despatches and receiving medals, and stars, and clasps. He retired in 1894 on a distinguished service pension. He had been Hon. Surgeon to the Viceroy of India and was a Fellow of the Punjab University and a member of the Irish College of Physicians.

Extraction of Needles from the Tissues.—The needle is first definitely located by means of the *x*-ray. The part is then oriented till the needle appears as a single point through foreshortening. An ink spot is made upon the skin corresponding with the position of the needle. This is repeated at the back. The pierced tissue is then pressed between the thumb and finger, applying one to each spot. The needle will then travel in the direction of the smaller end and finally will protrude through the skin.—*The Hospital.*

LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

MANILA, March 1, 1904.

In their efforts to reduce the high infant mortality among the natives, besides issuing some 80,000 circulars on the care and feeding of infants and issuing gratuitously sufficient flannel to protect the new-born children of the indigent, the sanitary authorities will hereafter supply to all applicants dressing packets containing a suitable piece of sterilized gauze, lengths of bobbin, a small quantity of boracic acid and safety pin. The whole is put up in paraffin papers in an aseptic packet, for use as a dressing for the umbilical cord, in the prevention of tetanus infection, which is a potent factor in the infant mortality in the Philippines. Full instructions for use will be printed in Spanish and Tagalog on the outside of the packet, the use of which will be popularized by every possible means. At present, the value of a cleanly—let alone an aseptic—dressing of the umbilical cord is not understood, and any dirty cloth is regarded by the poorer classes as making a satisfactory dressing for the umbilical wound. The cord is handled with uncleanly fingers, washed in dirty water, seared with a candle-flame, and frequently dressed with ashes or even dry earth as an absorbent. Under such conditions and with the general distribution of tetanus germs, the wonder is not that so many children die of tetanus infection of the umbilical wound, but rather that so many escape such infection.

The Bureau of Government Laboratories has recently published a paper by Dr. James W. Jobling, Director of the Serum Laboratory, on "Rinderpest in Cattle and Carabaos in the Philippine Islands," as Bulletin No. 4, of 1903. The paper is primarily intended for the information of cattle breeders and shippers, and includes the symptomatology, prophylaxis, and treatment of the disease. As the immunization of all animals now on the islands and hereafter to be imported is contemplated by the Government, coöperation to this end by cattle-owners is urged.

The disease apparently first appeared in the Philippine Islands in 1882. There is an incubation period of three to ten days. The chief symptoms are fever, congestion of mucous membranes, discharges from the eyes and nose, abdominal pain with diarrhœa, and sometimes an eruption on the back, loins, and mammæ. The great majority of animals attacked die, and within the past three years it has been estimated that as high as 90 per cent. of the bovines in the islands have died from this disease. The cause is unknown. The disease is conveyed to but a limited extent in running water or in the air. The usual method of transmission is by infected ground, or by any articles with which the discharges of diseased animals have been brought into contact. Hides, bones, and flesh of dead animals convey the disease. A great source of loss among cattle shipped into the islands is due to infection harbored on cattle ships which have not been disinfected. The disease is readily conveyed by inoculation, as little as one-tenth of a cubic centimeter of blood from a rinderpest animal giving the disease when injected subcutaneously. Human beings do not contract rinderpest. Preventive measures consist of early isolation and of disinfection of the place, where isolated, after conclusion of the case, by covering with straw and burning over. The agent of the disease can be carried on the shoes from an infected site. An infected herd should be moved to new pastures, split up, and the temperature of each animal taken daily. The bodies of dead animals must be burned. The hides, if saved, must be disinfected in carbolic acid solution and dried thoroughly in the sun. The various methods of immunization are discussed. The method in general use in the Philippine Islands consists in injecting an animal which has recovered from rinderpest with rapidly increasing doses of blood from animals sick with the disease, until the blood of the first animal has acquired a high degree of immunizing potency. The blood is then drawn, the serum separated out, and 15 to 50 c.c. injected subcutaneously, in the animal to be immunized, on one side, while 1 c.c. of virulent blood is injected into the other side. The mortality from this operation is from 2 to 10 per cent., but the immunity produced is very lasting. No treatment proves of any value in the disease, except the injection of blood serum from animals recently recovered from the disease.

An excellent paper on "The Influence of Tropical Conditions on Diseases of the Oral and Dental Tissues" was lately read before the Manila Medical Society by Dr. Louis Ottofy, who has had a long experience as a dentist in Japan, China and the Philippines. In respect to the condition of the mouth in the indigenous races, Dr. Ottofy notes pigmentation of the mucous membrane and reduced activity of the salivary glands; in an experience with a large number of persons who had leprous tubercles around the mouth, he found that the resultant ulceration was well defined and stopped short when the integument became continuous with the mucous lining of the mouth. In far advanced cases of leprosy, however, the mucous membrane became involved. As a result of the examination of the teeth of five hundred Filipino school children, he found no difference in structure or condition as compared with white children, but among adult Filipinos the condition as to caries was distinctly better, he believes as a result of the use of tobacco and betel nut chewing. The proneness to caries, which among Caucasians continues up to the twenty-fifth year, is shortened to the sixteenth or eighteenth year among the Filipinos. Externally, the teeth of betel-nut chewers were found to be more eroded than among non-habitués of this habit. Among the unacclimated, Dr. Ottofy finds no abnormal condition of the teeth not directly traceable to illness, hardship or deprivation, and on the other hand finds that certain fungous growths, as the oidium albicans, which in the temperate zone possesses grave possibilities, have here no special pathologic importance. With respect to the soft tissues, however, he finds a marked loss of tone, turgidity of the gums, and a tendency for the latter to retract and fall away from the necks of the teeth, leaving pockets for the retention of extraneous matters, and in the absence of scrupulous cleanliness causing the gums to become very sensitive. Pyorrhœa alveolaris becomes much worse and more resistive to treatment when found in persons lately arrived in the tropics. Dr. Ottofy finds an undescribed form of tropical ulcerative stomatitis, which is not uncommon among the unacclimated and those weakened by disease. In sixty-seven out of eighty-three such cases, the patient had previously suffered from malarial fever, dysentery, spine or similar wasting disease. The disease is rare among sailors, but common among soldiers, or marines quartered on shore. Much improvement follows a change of climate, and spontaneous cure results from even a short sea voyage. Dr. Ottofy does not believe that the teeth of new-comers decay more rapidly than in the temperate zone, except where the new conditions do not permit of the usual attention to the teeth. Odontalgias are, however, not only more frequent, but refractory to treatment. Wounds within the mouth do not readily heal, and abscesses are liable to occur and run a tedious course. The use of local anæsthetics he condemns because of the practical impossibility of preventing alveolar infection and abscess from their use.

The Board of Health and Municipal Board are represented on a joint committee which is now engaged in mapping out the most insanitary and congested districts of Manila, with a view to the relief of such congestion, the removal of habitations of unsuitable character and the erection of tenement houses, operated by the city, in their place. The insanitary homes of the poorer classes are of nipa or solid masonry. The former are the more easily dealt with, as they rapidly decay, are greatly exposed to destruction by fire, and are so cheap in construction that their condemnation and removal when insanitary cause little opposition. Within certain limits the construction of nipa buildings is prohibited by law, and those now existing are rapidly disappearing, when the vacant space thus secured can be built upon only with the approval and under the direction of the sanitary authorities. The solid houses of masonry construction of the Spanish type are quite a different proposition and create a most serious sanitary problem. As a general rule, these houses are built without any reference to ventilation, light and dryness, have no proper facilities for the disposal of excreta, refuse and storm water, and are honeycombed with rat burrows. Such houses are usually located on more valuable sites near the center of the city, and as a result of the tremendous rise in rents which has occurred since the American occupation, the necessities of the poor furnish an inducement for overcrowding that did not exist in as great a degree during Spanish days. Such houses are built to defy time, fire, and earthquake. Their proper alteration into sanitary habitations is a difficult and, in many cases, impracticable task, and their removal would be a most costly procedure. The present congestion will be largely removed when the new electric street car system, now under construction, is completed and poor people are able to live on the outskirts of town; while the completion of the tremendous docks, work on which is more than half done, will entirely change the location of the business center of Manila and furnish an additional reason for the relative depopulation of the present slums. Even with the relief of congestion which may be expected to occur from the above causes within the next two years, the present habitations of masonry will have to be provided with sanitary facilities or be removed, and it is concerning this question that the committee above referred to is appointed largely to investigate.

To assist in the work of municipal improvement a civic federation of a large number of American, Filipino, and

Spanish residents has lately been formed, a considerable part of the membership of which is composed of ladies. This society has at present largely devoted its energies to securing more parks to furnish breathing spaces for the poor, and has secured the offer by the Bureau of Education to the city of the buildings and ground formerly used as the exposition grounds and occupied by the higher grade schools for the past five years. In response to a popular demand, a large number of streets in the better residential part of town are to be widened and straightened, and funds have been appropriated for that purpose. Some of these Spanish streets are so narrow that two carriages can scarcely pass, and with the operation of the new electric cars over them in their present condition, wagon transportation would be largely interfered with. In response to the efforts of the sanitary authorities, an awakened interest in civic improvement is noted all over the city. At the present time much low land is being filled, drains cut, esteros straightened, new streets and parks laid out, and roads repaired. The tracks of the electric car line have been laid in large part, plans are completed for the drainage and sewerage of the city, and work on the new water supply is about to be commenced. The greatest single undertaking, and one which will make Manila one of the chief ports of the Orient, is the building of the shipping docks, so that vessels can unload directly on wharves and into the cars to run on the projected tracks. At present, everything has to be brought ashore in lighters, and the cost of lighterage from ship to shore is greater than the cost of transporting the same article from San Francisco to Manila Bay, not considering the greater delay and the possibility of the interruption of the work by storms during a large part of the year. At present, a stone breakwater has been laid to protect the anchorage, and within this a space of about two hundred acres has been enclosed by a stone wall and is being filled in by dredging out the harbor. Already there is dry ground where a year ago there were sixteen feet of water, and the level of the ground in this area is now at about high water mark. It will be filled in to a level eight feet above low tide, and the work of filling will be completed in about eight months more. The land thus gained will be leased for warehouses, and stone piers built out sufficient to accommodate all the ships which may visit what will be the greatest port in the Orient. The breakwater will be extended so as to enclose the ships in a protected harbor, safe against any typhoon. In the meantime, the necessary earth for filling is being secured by dredging out the harbor to a uniform depth of thirty feet, removing the foul deposits of centuries and creating a roadstead in which the largest ships can safely anchor. This work will be wholly completed within two years and a half, and will entirely transform the city from a commercial standpoint, which in turn will exert a marked influence upon the size of the city, the trend and density of population and the lines and facility of communication. These harbor works will stand as a monument to American ability and energy, and will have a profoundly favorable effect upon the city and through it upon the islands as a whole. Even the most obstinate and hostile of the natives cannot but admit that the Americans are bringing about improvements which the Filipinos themselves would never have accomplished. Within three years the culmination of the work now under way or projected will leave Manila a city transformed.

THE QUESTION OF PRIORITY.

To the Editor of the Medical Record:

Sir: In your issue of April 30, 1904, you have a clipping from *Zentralblatt für Gynäkologie* describing an operation for suspending the uterus by the round ligaments by Bardescu which he claims or leaves to be inferred is original. I wish to say that the method is in most of its features identical with one I devised, published, and have been practising since 1899. It was first described, I think, in the March number of the *American Journal of Obstetrics*, 1900, since which it has been exploited on many occasions by different operators and writers. I simply wish to claim for this country that which is her due and of which she is so often deprived—the credit for original work and investigation. D. Tod Gilliam, M.D.

Columbus, Ohio, May 6, 1904.

Improper Vaccination Certificates.—The Health Commissioner of New York City has issued a warning against vaccination certificates which he has learned have been issued in large numbers by certain physicians for a fee sometimes as low as ten cents. Such certificates, he says, will not be considered at the public schools.

Progress of Medical Science.

The Boston Medical and Surgical Journal, May 5, 1904.

Action of Resorcin.—C. F. Clark offers the results of his experience in the use of resorcin in the case of eczema. He believes that in the inflammatory stage of eczema accompanied by intolerable itching, burning or smarting or all three, resorcin is perhaps almost infallible. Its action is that of an anodyne. It reduces inflammation and soothes irritation. It may be applied either in solution or as an ointment. The writer uses a 4 per cent. solution with success. The application may be made on strips of linen or lint. The ointment may be made by adding 20 gr. of resorcin to an ounce of zinc ointment, or cold cream. Sometimes from 5 to 10 gr. of salicylic acid may be added to the resorcin ointment. This is to be applied every night or oftener. The resorcin and salicylic acid should be dissolved in alcohol to assure perfect union; the zinc ointment is warmed over a slow fire, and the alcoholic solution of the two added, or if powdered, rubbed together and sifted in. The whole is covered slowly and stirred till sufficiently cold. Constitutional treatment must not be neglected, for resorcin is not a specific. The writer believes that this drug may be used in the treatment of all inflammatory surfaces, such as erysipelas, erythema, and herpes zoster. The application must be varied to suit the individual case.

Use of the Sphygmomanometer.—H. F. Vickery offers some interesting observations that he has made as a result of the study of a large number of patients. He believes that the measuring of the pulse-tension is a useful addition to the modes of studying medical cases. The existence of high tension was discovered by the sphygmomanometer in cases in which he had not suspected it. It has been said that when the radial artery is of normal size, one can tell the tension pretty reliably, but if the artery is not more than half its normal caliber, very good clinicians will fail to appreciate a tension of from 20 to 60 mm. of mercury above the average. The high tension was present in all the cases of nephritis. It is said not to be present in a purely parenchymatous nephritis. The complication of heart lesions does not present the high tension. Heart lesions are quite consistent with high tension apart from any nephritis. In cases of aneurysm, the two radial arteries differed in several cases. In one case there was no difference. There is said to be a disparity in the two sides in hemiplegia. All sorts of cardiac lesions are capable of presenting a high tension. The writer calls attention to the explanation of the clinical experiences that digitalis often will not work in such cases until a purge has been given. This unloads the capillaries so the left heart when it is encouraged to work harder does not "press against a stone wall." As to the value of tension in detecting a perforation in typhoid fever, the writer believes that if one is going to be guided by the sphygmomanometer with regard to the advisability of laparotomy for perforation, the patient must be kept track of from the beginning of treatment. He gives instances of cases of typhoid fever in which the tension was higher than normal.

Journal of the American Medical Association, May 7, 1904.

Multiple Loose Bodies in the Knee-joint.—The patient of J. P. Lord was a man of thirty-three years who had had attacks of inflammation of the left knee-joint at intervals of from two to four years, extending over a period of fourteen years. The operation performed for their removal is thus described: An incision was made as for a Volkmann resection of the knee. The patella was sawed transversely, the lateral and crucial ligaments divided. The whole articulation was thus exposed. Four bodies were removed from above the patella. One of these was the large one of mulberry shape. Four were removed from under and beside the patellar tendon, and two from the posterior part of the joint, behind the crucial ligaments; these two were, in fact, posterior to the condyles, and much effort was required to dislodge them by the use of curved scissors. The bodies by the patellar tendon required removal by the scissors on account of pediculated villous attachments. In the localities of the attached bodies the synovial membrane was much thickened and hyperæmic. On the central surface of the inner condyle the cartilage seemed fibrillated, bruised, and torn, as if by the impingement of a body between the joint surfaces. The patella was wired in the approved manner. The ligaments were sutured with chromicized catgut and the skin with plain catgut. Small gauze drains occupied the dependent angles of the incision. A dry gauze dressing was used and a plaster-of-Paris interrupted splint was applied, reaching to the perineum. The patient made a good recovery, but later, owing to impaired motion of the joint, forcible flexion was made under anæsthesia. Some four months after operation there was about 30 per cent. of the normal range of flexion and no irritation in the joint.

Medical News, May 7, 1904.

The Influence of Bovine Tuberculosis on Human Health. Masyck P. Ravenel concludes that at the present time e weight of the available evidence is in favor of the w that the chief source of infection in children, as well n adults, is the human tubercle bacillus, and that the al of entry is the respiratory tract. It has, however, n proven conclusively that the bovine tubercle bacillus sponsible for a certain proportion of the deaths from rculosis in children, and there is strong evidence at l to show that the number of children infected from ne sources is quite large. Whether the number be e or small, it is none the less our duty to guard against se of milk from tuberculous cattle for food.

e Diastolic Murmur in Diagnosis.—Austin W. Hollis res that the study of the diastolic murmur presents e difficulties than are met with in the systolic variety, ough in its usual form, it is simple and clear, and its e time and quality instantly reveal the diagnosis, no mur can be more elusive in its site and intensity. possibilities of its characters are so numerous that defy both description and diagnosis. Eight varieties be recognized. The causes are aortic and pulmonary ficiency, persistent ductus arteriosus, aneurysms, l stenosis, cardio-respiratory influences, pericardial pleuro-pericardial changes. In aortic insufficiency, the sity of the murmur varies greatly. The site of the mur is not a fixed one in every case. The cause of the ing point of maximum intensity is most interesting. n the murmur has its point of maximum intensity the aortic area it is undoubtedly due to vibration of ortic ring, but when it is elsewhere it must be caused e impinging regurgitant stream producing vibration at part of the wall of the ventricle where it strikes, because of the mechanical differences at the point e leak the direction of the regurgitant stream t constant. A musical quality is not uncommon. ulmonary insufficiency the diastolic lesion is far e constant in its quality and site than that of c insufficiency. A musical quality is exceedingly The maximum intensity of the murmur is s just to the left of the sternum in the second or spaces; it is transmitted by the wall of the right icle and unless intense is not heard at the apex. ersistent ductus arteriosus the diastolic murmur is infrequent and resembles that of pulmonary insuf- cy in quality and site, but is usually shorter and more inuous with the systolic. Aneurysmal diastolic mur- s are of two kinds. The first is due to an actual c insufficiency. The second is quite uncommon and used by the blood being forced out of a distended rysmal sac through its narrow opening during the tole. In initial stenosis, three varieties of the diastolic mur may be found. The presystolic has its maximum sity always at the apex. The second murmur is d between the apex and the end of the sternum. The l murmur is heard just inside the apex and sometimes the end of the sternum. The diastolic cardio-respira- murmur is very difficult of diagnosis. In pericarditis, systolic and diastolic murmurs are heard at some e during its course. The writer gives the history of al cases which illustrate some of the difficulties hich he has called attention.

New York Medical Journal, May 7, 1904.

venile Tabes.—A case of this nature is reported by ed Gordon, his patient being a girl of seventeen years presented from infancy a brachial monoplegia, bably of poliomyelitic origin. According to the author, case is of especial interest for three reasons: (1) presents a rare example of tabetic manifestations de- oped in a patient who showed symptoms of an acute erior poliomyelitis of infancy. All the cases known those of progressive muscular atrophy with a rare olvement of the pyramidal tract (amyotrophic lateral rosis). (2) It puts on record a new case of venile tabes. (3) It also shows that hereditary syphi- tabes, and acquired syphilitic tabes are identical in ir symptomatology.

The Significance of Parenchymatous Change in the dneys.—The conclusions of H. A. Tomlinson, based on nical experience largely verified by the study of similar nditions, both experimentally and clinically, in the wer animals, are: That there is as much difference in e kidney capacity of different individuals as there is the capacity of their other vital organs and the rvous system; that some individuals are born with de- ctive kidneys, not necessarily anatomically incomplete t functionally incapable; that in these individuals a ronic degenerative process is set up early in life; that ey are always, to some extent, the victims of chronic utointoxication, because of imperfect elimination; and that in them the irritation resulting from the retention of the waste products of retrograde metabolism keeps up a chronic congestion in the kidneys, so that from causes which do not seriously affect the ordinary individual, there may arise, and does arise, acute involvement of the parenchyma of these organs, checking elimination, and resulting in more or less explosive outbreaks involving the general organism, and especially the nervous system.

American Medicine, May 7, 1904.

A Modification of Existing Methods for Staining Flagella.—O. P. Johnston presents the following summary of his paper: Those things which seem to insure a good preparation are: Clean cover-glasses; but little organic matter in the film to stain and a heavy background; avoiding fixing the film in the flame, but allowing the mordant to fix it; avoiding heating either mordant or stain on the films, as it tends to produce a precipitate and background. Finally, the all-important prerequisite for staining flagella is to have a film which contains the organisms with flagella extended, and with this one condition fulfilled, no special technique is required other than the use of a mordant. If these conditions are satisfied, no special difficulty will be experienced by any one in staining the flagella. Failure to stain flagella usually means failure to get them in the film to be stained. It has been the experience of the writer that it is practically as easy to stain the flagella as the organism itself. In general, conditions which would seem to lower the irritability of the organisms, tend to give the best films for staining. Such conditions are an even temperature, avoiding sudden changes of temperature in preparing the films, avoiding jarring and allowing the organisms to remain in sterile water for several days or weeks before making the films.

Two Fatal Cases of "Landry's Paralysis," with Autopsy Findings in One of Them.—Theodore Diller reports these cases. In the first, the clinical manifestations ran their course in about nine weeks. The symptoms of ascending motor paralysis proceeding to an extreme degree and producing death by respiratory paralysis, the late appearance of tenderness and pain, the freedom from involvement of the sphincters until five days before death, the unclouded mind all form a most striking symptom-complex. Aside from the rather long course, it is almost the classic picture of Landry's paralysis. Post-mortem examination showed great alteration of the nerve cells in the anterior horns of the lumbar region. The left sciatic and ulnar nerves were partly degenerated. The alteration was that of multiple neuritis. The illness of the second patient began with a severe, sudden pain in the small of his back. It gradually grew less and had about disappeared at the end of ten days, when be began to lose strength in the legs. There was a progressive paralysis, later involving the arms, and finally the nerves innervated by the bulb, this last involvement causing death about six months after the date of the initial paralysis. During the first four months, the disease was of a purely motor type. There was great atrophy. The writer states that this case may be regarded as one of multiple neuritis predominantly of the motor type. But in view of the post-mortem findings in the first case, of the atrophy, of the ascending type of the paralysis and bulbar involvement, he thinks it very probable that a post-mortem examination would have revealed degenerative changes in the motor cells of the cord and bulb. He thinks it likely that the entire lower motor neuron was involved, as in the first case. The case presents clinical features different from those seen in ordinary multiple neuritis, not only in its predominantly motor character but especially in its feature of ascending paralysis. The writer cannot explain the sudden initial pain. Except in its long course, the case is a highly typical one of Landry's paralysis.

The Lancet, April 30, 1904.

Eye-strain as a Cause of Headache and Other Neuroses.—The conclusions of Simeon Snell are as follows: (1) Eye-strain is the cause of a large proportion of headaches, often of a very aggravated character. (2) Various other neuroses are met with in association with headache, and among these may be mentioned the following: mental depression, nausea, indigestion, vomiting, insomnia, giddiness, choreiform movements of the eyelids and face, etc. (3) Relief is afforded to these conditions by correcting the error of refraction which can be ascertained only after careful examination. (4) For such examination a mydriatic is absolutely essential. (5) Frequently no complaint is made of defect of vision. (6) The ametropia is frequently of low degree, 61.2 per cent. of my cases needing 0.75 D. cyl. and weaker. (7) A cylinder of 0.25 D. is of great value (8) Anisometropia is frequently present and requires proper adjustment.

Recent Studies in the Tissue-lymph Circulation.—George Oliver has studied the topics outlined in the title of his paper, noting that the ingestion of food invariably raises the arterial blood pressure and that there is a progressive rise in the percentage of corpuscles and hæmoglobin for an hour after eating, the normal state being reached again about three hours later. There are also similar digestive variations in the specific gravity of the blood, together with variation due to augmented respiratory change and a rhythmical variation of muscular contractibility after food. The author then inquires as to the mode of production of the digestive exudation of tissue-lymph. His data show (1) that the food constituents themselves (fats, carbohydrates, and proteids) do not possess the power of starting the mechanism by which lymph is dispensed to the tissues throughout the body; (2) that nature associates with our foodstuffs small quantities of certain active substances which bring into play that mechanism, though these substances have no practical food value; and (3) that man can artificially increase this natural lymph stimulation by the use of salt and beverages. Oliver further believes that such bodies as uric acid, xanthin, glycogen, and sodium chloride perform an important function in nutrition, for during digestion they act as distributers of lymph to all the tissues, an office which the nutrient constituents themselves are incapable of discharging.

The Treatment of Muco-membranous Colitis.—De Langenhagen notes that the proper treatment of these cases is properly hygienic and that drugs are almost always inefficacious; at times they are even harmful, owing to the alcohol or other irritating substances that are often mixed with them. The physician is, however, obliged to fight against the painful phenomena that accompany colitis, for the patient asks for some relief. To this end belladonna in the form of suppositories should be used, or taken internally in the form of tincture or pills (one grain of the extract in five or six pills for every twenty-four hours), or frictions with an ointment containing mercury and belladonna can be made if a calming effect is desired, or with turpentine if a somewhat stimulating action is preferred. Very hot, large poultices, sprinkled with laudanum, placed on the abdomen also succeed very well; or in the same way applications of large compresses, dipped in a very hot decoction of poppy heads, covered over with impermeable taffeta and with strips of flannel, and kept on the entire night. Indian hemp calms the intestinal spasms very well. A good elastic belt is necessary to hold and to lift up the abdomen in patients who have noticeable enteroptosis. The physician should be chary of using drugs against the dyspeptic phenomena that accompany colitis, since generally these troubles are lessened as the state of the intestine improves; but, according to the case, a little hydrochloric acid may be used, or alkalies, absorbent inert powders (charcoal, chalk, magnesia), and nux vomica.

So-called "Spontaneous Fracture" of the Femur from Secondary Malignant Disease with Subsequent Firm Bony Union.—The patient of T. M. Thomas and B. G. Fiddian was a married woman of forty-seven years whose left breast had been removed for scirrhous cancer fourteen months previous to the fracture. She had had leg pains regarded as "rheumatic" and these were definitely localized over the site of the future fracture, being due presumably to implication of nerve fibrils. One day, while stooping to pick up something from the floor, the left thigh suddenly snapped. Examination revealed a fracture at the juncture of the upper and middle thirds. Seven weeks later it was found that firm union had taken place. The patient died of recurrence of the cancer in breast and liver about ten weeks after the accident. At the autopsy the site of the fracture was cut down on and the upper half or so of the femur was removed *en bloc*. Such firm union of the fragments was found that they could not be torn apart even on the exertion of considerable manual force. A mass of cancerous growth was found wrapping the upper third of the femur loosely round and eroding it at the site of fracture—*i.e.* the upper end of the lower fragment and lower end of the upper—but the rest of the femur was uneroded. The conjoined mass of callus and malignant tissue cut like a scirrhus but with a gritty sensation at parts. It apparently extended from a chain of malignant glands which passed down from behind Poupart's ligament and seemed to have acquired an attachment to the periosteum. There was distinct overlapping of the fragments and to this union seems to have been due, for by this means unimplicated portions of periosteum were brought into apposition, not the diseased extremities of the fragments.

Deutsche medizinische Wochenschrift, April 14, 1904.

Syphilitic Changes in the Vagina.—Rille thinks that the primary lesion is more frequent than other observers will acknowledge. He has seen it in twenty-one cases, and thinks that the comparative rarity is due to the firm character of the squamous epithelium of the vagina, to the mass of secretions which probably dilute the virus or render it powerless, or to the mobility of the vaginal walls. The vaginal chancre is usually small, slightly indurated, and of rather short duration, and the latter characteristic accounts for their being so infrequently observed, in the author's estimation. The inguinal glands are only involved when the lesion is situated in the anterior third of the vagina. Soft chancres are equally infrequent but can be more readily diagnosed. Secondary exanthemata are undoubtedly rare. Rille has never seen a macular syphilide, but has seen the papular lesion which becomes particularly well marked during pregnancy. Chancre of the vaginal portion of the cervix is not uncommon. It is more usual on the anterior lip, and when these gape, the lesion may extend into the canal. He describes the lesions very carefully and draws attention to the necessity of examining this region in suspected cases.

Operative Results in Peritonitis after Appendicitis.—Trendelenburg discusses indications for the surgical treatment and the prognosis in peritonitis resulting from appendical inflammation. He bases his observations on statistical evidence presented by a series of eighty-six cases treated by operation. As it is impossible to define the limits between circumscribed and general peritonitis, for one merges into the other, he does not recognize the distinction. Of the eighty-six cases, 64 per cent. died and 36 per cent. recovered. It was also found that the prognosis was about twice as favorable before the thirty-fifth year than during later life. He states, moreover, that the chances are better for the operation after repeated attacks than if done during the first attack. The origin of the peritonitis also has an important bearing on the prognosis. It seems that when the infection comes from the perforated appendix, the prognosis is more favorable than when it dates from a localized appendical abscess, even when the latter has been shut off in some other part of the abdomen. The time of operation is very important. The author's figures show that if the operation is done on the first day after the peritonitis has begun, four-fifths of the patients may be saved, on the second day, about two-thirds, and on the third day, none.

Unusual Outcome and Sudden Death in Typhoid Fever.—Curschmann describes a number of irregular cases of typhoid fever in which death occurs during what are apparently the first days of the disease. He claims that these are instances of ambulatory typhoid, so called, and that the disease has been present longer than was suspected. The majority of these cases end fatally from intestinal hemorrhage or perforation peritonitis. Curschmann is inclined to believe that the latter complications occur more frequently in the ambulatory form of typhoid fever than in the typical cases. This seems mainly due to the fact that the patients are more exposed to errors in diet and bodily exertions. Hemorrhages come on suddenly without any premonitory signs even more often than perforations, but as the latter almost always end fatally, they receive greater attention in mortality statistics. Hemorrhages end in death in only about 30 to 40 per cent. of cases. Other conditions which bring on sudden death are quite rare when compared with the intestinal lesions. He mentions a case of pulmonary embolus and one of septic metrophlebitis. Another unusual type is the hemorrhagic form, of which the author has seen six cases. This is marked by hemorrhages in the skin and internal organs, similar to what is seen in certain other acute infectious diseases. Children seem to be most often affected by this type, and from his own observations he believes that alcoholics are also predisposed.

Dangers of Intrauterine Injections.—Zweifel reports a case in which he tried to induce abortion for cardiac disease by means of Kunne's method, which consists of intrauterine injection of sterile water under the most careful antiseptic precautions. In this case the patient went into sudden collapse, marked by convulsive twitchings, and followed by hæmoptysis, hæmoglobinuria, chill, and rise of temperature. The woman recovered. The entrance of air and the absorption of toxic materials could be excluded, but the author thinks that the most likely explanation of the symptoms depends on the fact that the water dissolved some of the blood in the uterus, caused the formation of clots, leading to pulmonary infarct and hæmoglobinuria. This train of symptoms has been observed in animals, in whom water was injected into the circulation. The pregnant uterus is particularly susceptible to this complication owing to the condition of the blood-vessels, and less danger is present during the puerperal state. In gynecological patients, in whom the mucous membrane is intact, the injection may sometimes

be followed by attacks of colic, and later on by peritonitis. This was especially marked when irritant applications were used. Zweifel believes that the materials can find their way into the abdominal cavity through the tubes, for in a case of carcinoma uteri he observes that a disinfecting solution injected into the cervix came out through the fimbriated extremity of the tube. He therefore urges that in all cases only a few drops of a liquid be employed when making applications to the interior of the uterus, and when injections of a larger volume are required, the os must be kept well dilated so that proper return flow is provided.

Berliner klinische Wochenschrift, April 18, 1904.

Contributions to the Study of Hematology.—J. Mitulescu has made some practical experiments in order to determine whether in making quantitative hæmoglobin tests, there is any essential difference between the results obtained by methods based on colorimetric or chemico-colorimetric observations. He suggests that in each case the readings be made quickly, as the color changes quite rapidly. A series of observations in twenty-three cases shows that the results obtained are practically parallel, with the exception of those instances in which the hematin became dissolved by the action of hæmolytic substances, in consequence of which the iron content of the blood serum was increased, or when evidence of other coloring matters of the blood was prominent. In ordinary cases, therefore, the colorimetric method is sufficient, but when the presence of a hæmolytic process is suspected and an accurate analysis is necessary, both methods are required.

Constitution of Tetanolysin.—Hans Sachs has published the results of observations which are based on the following questions: (1) During the reaction between tetanolysin and antilysin, assuming that the mixture contains equal parts of toxin and antitoxin, is there any variation in the condition of equilibrium, and (2) in consequence of this, is the reaction between these two substances reversible? As the result of an elaborate series of experiments with these two bodies, he claims that there can be no question that the tetanolysin is an homogeneous substance, which unites with the antitoxin in a manner similar to that which takes place in the reaction between boric acid and ammonia. This fully opposes the view taken by Madsen and Arrhenius, who ascribe the process which takes place between tetanolysin and antilysin entirely to a reversible reaction.

French and Italian Journals.

An Abnormal Location for the Lesion in Appendicitis.—Routier gives the history of this case. The general condition did not seem to be serious. The temperature was scarcely above normal, although the pulse was 108. There was a decidedly painful spot in the iliac fossa; the abdomen was not distended, and it was impossible to learn from the patient anything about the action of the bowels. At the operation, Routier, not finding the appendix in the usual place, was obliged to explore the ileocæcal angle of the abdomen. He found that the appendix was entirely included between the two layers of the mesentery from which it could be separated only by incising the inferior layer. The appendix was gangrenous, and was near the stage of perforation. The appendix was excised and the wound was drained. Recovery took place.—*La Presse Médicale*, April 16, 1904.

The Finsen Method in the Cure of Lupus.—Eugenio Calvello writes of his experience in the use of the ultra-violet rays for the cure of lupus, etc. The two properties of actinic light, the stimulating and the bactericidal, render it of the greatest use in the cure of this most chronic, tenacious, and disfiguring malady. But the Finsen method is difficult of application and expensive, and the management of a current of 80-100 ampères is not easy. From the apparatus emanate, as well as the chemical rays, numerous heat rays, which are capable of injuring the patient. In place of carbon electrodes an especial arrangement has been made by Bang with iron electrodes cooled by a moving stream of water. This the author has found of great use in the treatment of his patients. Compression is not necessary to eliminate the blood from the tissues, and the electrode can be placed quite near to the diseased area. He mentions two obstinate cases of lupus that had resisted all efforts by caustics, cautery, etc.; these were treated in his clinic, one receiving eighty, the other forty-eight treatments. Both resulted in a perfect cure, with a perfectly normal skin overspreading the former diseased and disfigured area.—*Giornale di Elettricita Medica*, March and April, 1904.

A Case of Angioma Cavernosa of the Trapezius Muscle.—Roberto Alessandri describes a case observed by him of angioma of the right trapezius, and gives an account of all the cases to be found in literature, 77 in number. The affection is a rather rare one. Lubarsch says that the tumors of striped muscle are rare; cavernous tumors are the most frequent, and arise from the connective tissues. Four varieties may be distinguished, capillary, venous, cavernous, and arterial. The author's case occurred in a young, healthy, married woman. It commenced as an indolent swelling above the clavicle on the right. It was the size of half an orange, with a large base, compressible and not pulsating. The superimposed skin was quite normal. The tumor was successfully removed, and found to originate from the trapezius muscle; it was cavernous in structure, divided by fibrous septa into lacunæ containing endothelial cells; the cavities were for the most part empty, but some contained normal blood.—*Il Policlinico*, March, 1904.

Thermogenesis in the Electrostatic Bath.—Raffaele Pisani has arranged an apparatus for estimating the heat produced in the bodies of patients while undergoing the electrostatic bath. The apparatus is provided with a needle which registers the curve produced by the heat generated on a cylinder, in the form of a tracing, as the sphygmograph registers. He made the observations on perfectly healthy persons, who were directed to remain perfectly quiet while the bath was going on, so as not to interfere with the registry of heat production. Each bath was twenty minutes long. His conclusions are as follows: (1) Static electricity in the form of the bath increases the calometric curve; (2) this elevation is greater with the positive current and less with the negative, and is proportional to the duration and intensity of the application; (3) such an elevation is due to a greater production of heat, which is increased by the electric bath from a minimum of 10 calories to a maximum of 32 calories; (4) the electrostatic current produces an increase of temperature in the body, greater in the positive bath, less in the negative.—*Giornale Internazionale delle Scienze Mediche*, March 15, 1904.

The Action of Light Baths upon the Circulatory Apparatus.—G. Arienzo describes the effects of light upon the circulation. Carbonic acid elimination is increased by the action of light baths. The author's researches were made to ascertain the therapeutic effects of light baths in cases in which the heart was affected. They have been used in cases in which there were disturbances of the circulation, such as dropsy, hydrops, stasis from hypertension or hypotension of the arteries. Roth advises their use in obesity, when there are circulatory disturbances. They have been used in old persons with the cardiac phenomena of marasmus, or with aortic insufficiency, etc. They may be used to produce diaphoresis, since they do not produce a frequent pulse and respiration, while they do increase the fulness of both. The author took tracings of radial and carotid pulsation, and counted the pulse and respiration before the bath; he then administered the bath at 30°, increasing to 60°, and for 20-40 minutes. He found that pulse and respiration increased in number as the heat increased, for 20 minutes, and then began to decrease. In from 5 to 20 minutes the pulse and respiration returned to normal. Over the carotids there was a manifest increase in amplitude and rapidity of pulsation. Hence, the light bath, used even for 40 minutes, does no harm to the patient.—*Annali di Elettricita Medica e Terapia Fisica*, March, 1904.

Bacteriological Researches in Some Cases of Typhoid Fever.—P. Stefanelli and E. Cumbo have made very careful researches in twenty-one cases of undoubted typhoid fever, as to the presence of typhoid bacilli in the urine and its value in diagnosis. Some have supported the theory that the presence of typhoid bacilli is due directly to the disease; while others consider it to be due to a severe accompanying albuminuria due to renal complications. The authors examined most carefully twenty-one cases in the Medical Clinic in Florence, with regard to bacilli in the urine and in the blood; extending their researches to the colon bacilli and the bacilli of pseudo-typhoid. The Widal reaction was always demonstrated to be present. They conclude as follows: (1) typhoid bacilli are often found in the urine of patients affected with this disease, and their presence is of diagnostic value; (2) they are found even in cases in which there is no albuminuria; (3) they may be found at any period of the illness; (4) they may persist throughout the entire illness, or their presence may be transitory; (5) their presence has no relation to the gravity of the disease, or to the prognosis; (6) bacilli found in the blood and urine may have only slight agglutinating power; (7) we may find colon bacilli which will agglutinate in a dilution of 1.30, with serum of the same of another patient; (8) in some urines we get bacilli of the colon which may or may not agglutinate with serum; (9) there may be found typhoid bacilli in urine which do not correspond entirely with the Eberth bacilli; (10) these may be true typhoid bacilli even if they possess only slight agglutinating power.—*Rivista Critica di Clinica Medicina*, March 12, 19, and 26, 1904.

Poisoning by Sublimate.—Spillman and Blum report an interesting case. A young woman of thirty years drank liquid containing three grams of sublimate. She passed forty-eight hours without any symptoms save amaurosis. Then, suddenly, there appeared a fetid diarrhœa. Gradually, the stools became hemorrhagic. Symptoms of salivation developed, and also gingivitis. The face and tongue became œdematous. Convulsions came on, and the patient died twelve days after drinking the sublimate. At autopsy, gangrene of the cheeks and gums was found, œdema of the glottic region, two small ulcerations of the œsophagus, œdema of the stomach, enteritis, gangrene of the rectum, vegetations of the mitral valve, and a softening of the right occipital lobe. The two kidneys were large and white. The course of the case was most unusual.—*La Médecine Moderne*, March 23, 1904.

Glandular Cysts of the Pancreas.—F. X. Gouraud states that cysts of the pancreas are rather rare. It is an affection of adults, and is most often found between the ages of twenty-five and forty-five but it has been observed in the aged, and on the other hand Railton has reported a case in an infant of six months which was operated upon. As to the causes of this affection, trauma is a frequent one. In ninety-six cases recently reviewed by the writer, sixteen have been found in which trauma of some kind seems to have been the starting point of the cyst. It is hardly necessary to mention the processes, which lead to sclerotic pancreatitis; infectious processes such as typhoid fever, gastroenteritis, tuberculosis; or the toxic processes, such as alcoholism. Nearly always the malady begins insidiously with troubles of digestion, slight weakness and vague pains in the left hypochondriac region. It is during the first period of very variable duration when diagnosis is impossible. When the tumor appears it grows rapidly, and the functional symptoms increase while the phenomena of compression begin. At this time diagnosis and intervention are possible. This is the second period. If, however, intervention is not made, there develop cachexia, and vascular, and digestive troubles which are almost like those of large abdominal tumors. This is the third period, cachectic and terminal. Complications of pancreatic cyst are rare and of little importance. It is of itself a serious malady, and if intervention does not take place death comes at the end of a year or two. As to operation, one must be guided by the clinical variety of the cyst. Total extirpation is indicated if the cyst is accessible and well pediculated. On the contrary, the surgeon must be content with simple incision with drainage, which almost always brings about cure.—*Gazette des Hôpitaux Civils et Militaires*, April 2, 1904

Contribution to the Subject of Tetanus in Pregnancy.—Ferruco Griziotti details the case of a patient of thirty-six years, who had eight pregnancies, in the last five of which she was affected by tetanic seizures. All ended normally with five children. The first attacks began at the fifth month of the fourth pregnancy, with tonic contractions of the upper and lower extremities, occurring three or four times a day. The contractions were accompanied by severe pain, nausea, vomiting, lessened visual faculty, and diplopia; consciousness was preserved. The attacks were less frequent after the eighth month, and ended with parturition. There were marked trophic disturbances of the nails, which necrosed and fell off, but were soon reproduced. These symptoms recurred with each succeeding pregnancy, while in the intervals they were entirely absent, and her health was excellent. If at the time of pregnancy an Esmarch's bandage was placed about the arm a tetanic contraction would be produced. A simple digital compression of the nervo-vascular apparatus had the same effect; pressure or compression of the muscles of the face would cause contraction and a peculiar expression of face. The deep and superficial plantar reflexes were exaggerated. There was slight hyperæsthesia. Examination of the urine and digestive apparatus sho wed only normal conditions. Bromide of potash diminished the seizures. At the time of labor, when vaginal examination was made, it was observed that when the uterine contraction began, an attack was brought on. Increased galvanic irritability could be demonstrated in this patient. The theories of the etiology of tetanus in pregnancy are the nervous, infective, and the toxic. The nervous theory, maintained by Charcot and Raymond, attributes the contractions to hysteria. The author's case showed absolutely no stigmata of hysteria. No microbic agent has yet been found to account for the tetanus on an infective basis. There remains the toxic theory, according to which the contractions are due to self-poisoning of the mother by retained excretions. This seems the most rational of the three. Yet the examinations of the excretions in the author's case revealed nothing abnormal.—*Archivio di Ostetricia e Ginecologia*, February, 1904.

Relations of Ocular Affections to Organic Maladies.—M. E. Valude, in discussing the affections of the digestive apparatus, states that their effects on the eye act generally by means of an autointoxication, or by a generalised asthenia. Chronic affections of the digestive apparatus end often in a profound neurasthenia, with which ocular troubles characteristic of this condition are associated: accommodative asthenopia or insufficiency of convergence, nervous retinal fatigue, photophobia, ophthalmic migraine, and so on. It has been noted that patients afflicted with enteritis are sometimes subject to glaucoma. The affections of the liver have such a marked influence on vision that the discovery of certain special ocular lesions ought to suggest immediate examination of this organ. Conjunctival xerosis, hemeralopia with or without alterations of the fundus, and, in a slight degree, xanthelasma of the eyelids are seen. Affections of the pancreas do not directly influence the ocular apparatus. Disorders of the respiratory apparatus scarcely have any effect aside from mechanical, upon vision. As to blood changes, alterations in this fluid act directly or indirectly upon the eye. Anæmia affords a good example: In this trouble may be observed almost always quite a marked degree of accommodative asthenopia. Not infrequently in these patients are seen small papillary vegetations on the conjunctiva of the lower eyelid. In pernicious anæmia are found hemorrhages of the fundus of the eye.—*Le Bulletin Médical*, March 23, 1904.

Hemi-resection of the Elbow by Internal Lateral Incision.—Gangolphe reports the case of a patient aged twenty-seven years who had fallen upon her elbow two months previously. There had resulted a backward dislocation of the right elbow which her physician had been unable to reduce. The writer immediately made a hemi-resection of the elbow (the inferior extremity of the humerus) by a single internal lateral incision. The sigmoid cavity of the ulna, and the radial cup were filled up with fibrous formations as well as a growth of periosteum which the writer easily removed. Five days later the first dressing was changed and the drain removed. On the seventh day after the operation the wound was perfect. The movements of flexion and extension could be made at an angle of forty-five degrees.—*Lyon Medical*, April 3, 1904.

Semeiology of the Mastoid and Pre-auricular Ganglia.—Lamacq-Dormoy declares that mastoid adenitis, aside from the lesions of the scalp and adjacent skin, is a sign of inflammation of the rhinopharynx, and ought to claim the attention of the clinician, because he will be able by an early diagnosis to avoid the extension of the inflammation to the middle ear and to the mastoid region by means of appropriate treatment. The writer then gives a few notes of a case. The patient was a man of forty-three years, who had coughed for several months, especially at night, when lying down, and in the morning on getting up. He expectorated but little, was gradually growing thin, suffered from rigors, and the least exertion oppressed him. The writer found cough inspiration at the apices, but no other symptom. The patient denied having sore throat. Finally the writer made out small but very painful ganglia in the mastoid region as well as in the pre-auricular. He instituted a simple local treatment of the nasopharynx and the patient was cured in fifteen days.—*Gazette Hebdomadaire des Sciences Médicales de Bordeaux*, April 3, 1904.

Annals of Surgery, April, 1904.

Traumatic Asphyxia.—H. H. A. Beach and F. Cobb report a case of their own, studying also the minute pathology of the affection and summarizing cases previously reported—only six in number. Their patient was a man who had been caught by a moving freight elevator. He was unconscious for a few minutes after being released, and during his release it was stated that his face became black, that his eyes protruded, and that blood ran from his nose and mouth. It was apparent that he had been subjected to violent trauma, from the groins and buttocks to the mid-thoracic region. The lesions found are enumerated, and the authors pass to the condition of the skin. The face seemed to be dotted with countless spots, from black and reddish-black to blue in color, very close together, while between the spots were lines or areas, very minute, of normal appearing skin. These spots were plainest at the line of the hair on the forehead and close to the normal skin on the neck. The line of demarcation in the neck in front was sharp, the transverse line running through the inner ends of each clavicle; this can be seen in the picture. What has not been noted in any other case, is that the double triangle of the trapezius muscle was marked out very clearly. No retinal hemorrhages were found. A hæmatoma on the back required frequent packing, and finally free incision and packing. The discoloration of the skin faded rapidly after the third day, while the sub-

junctival discoloration went through the usual changes after any blood-clot. The patient made a good recovery.

Operation in Spinal-cord Injuries.—The advantages of surgical intervention in this class of injuries are thus enumerated by P. J. Mixter, and H. M. Chace who report two cases: (1) Operation removes depressed fragments of bone apparently lying against the cord; (2) It removes blood-clots; (3) Allows the escape of exudate and makes room for inflammatory thickening; (4) If extensive hemorrhage is present, either extral or intradural, it relieves pressure from the cord. Cases in literature have shown that degeneration from pressure appears within four days; if a cord is injured by crush and not totally destroyed, the continued pressure of a blood-clot may succeed in completing total destruction. (5) Traumatic spinal œdema may be of such extent as to demand greater space for enlargement of the cord to avoid further destruction of fibers; (6) There is absolutely no method by which one can early diagnosticate slight or great pressure of a fragment of bone, the pressure of a small or a large hæmatoma, whether there is a momentary pinch of the cord or constant pressure; (7) The fact that the cord looked normal in the two cases reported does not preclude the possibility that pressure had existed, nor prove that a condition had existed in which drainage and relief of pressure were not distinctly beneficial; (8) The patients do not suffer from any ill effect of the operation *per se*, the dangers of operation are very slight compared to the possible benefit to be derived therefrom; and the further satisfaction is obtained that the surgeon *knows* that continued pressure does not exist.

The American Journal of the Medical Sciences, May, 1904.

Experimental Studies of the Etiology of Acute Pneumonitis.—Augustus Wadsworth has been able to determine by means of an accurately controlled series of experiments which allowed of precise comparison, the effect of increasing or diminishing the virulence of the incitant, the pneumococcus, in systemically predisposed, in locally predisposed, and in both systemically and locally predisposed animals. These experiments, the writer declares, show that the excitement of diffuse lesions in the normal rabbit is extremely uncertain, and only possible in the predisposed rabbit when both the general and local susceptibility are increased and when organisms of comparatively low virulence are used. Thus, and owing chiefly to the fact that the lung surface acts as a barrier to infection, the development of acute exudative pneumonitis offers an especially clear example of the nice balancing of the essential condition determining infection. These conditions are, on the one hand, the specialization or virulence of the incident, and, on the other hand, the animal susceptibility, both local and systematic. Organisms of low virulence induce evanescent bronchial reactions; more virulent organisms, by a local infection, give rise to the more typical bronchopneumonic lesions; while organisms of still greater virulence, if confined to the lung, incite diffuse processes of the lobar type, but if not so confined and bacteriæmic infection occurs, the lung lesions are less marked and of the bronchopneumonic type. The extremely fine balance of these conditions essential to the formation of lobar lesions in normal as well as in predisposed animals is as yet, for practical purposes, beyond experimental control. The writer states, finally, that as a result of these systematic researches on normal and predisposed animals an entirely new procedure was adopted; the preliminary immunization of the rabbits so that extremely virulent cultures of pneumococci can be used without giving rise to bacteræmic infection. The experiments with this procedure showed that diffuse exudative lesions comparable to the lobar pneumonia of man may be incited experimentally in the immunized rabbit; and that in securing this result there are but two chief variable factors. The virulence of the incitant and the immunization of the animal; both easily and accurately controlled by the routine technique of the modern laboratory.

Nasal Syphilitic Tumors.—Max Toeplitz declares that the tertiary manifestations of syphilis, in the nose the most frequent, are often seen very early. The anatomical lesion is a gummous infiltration of the mucous membrane, dependent affection of cartilage, periosteum, and bone, and simple infiltration, with softening, ulceration, either from without, inward, or inversely. The favorite seat of the infiltration is the septum. The tumors are either extremely large gummata or so-called granulomata. The writer gives an account of several patients afflicted with these growths. These tumors obstruct the nose when large enough and discharge fibrinous, smeary, and purulent secretions. They cause pain in the head, face, shoulder, and paralytic weakness in the arm. They are of variable size and are implanted upon the mucous membrane with a broad or pedunculated base. They are red, reddish gray, not quite smooth, and show frequent erosions but rarely ulcerations. The tissue is boggy, brittle, still without tendency to decay, its main distinction from gumma. Many histories could be related in which the microscopical examinations revealed apparently a sarcoma which disappeared under anti-syphilitic treatment. The diagnosis of these tumors is difficult if the patients do not show other syphilitic signs and the history does not furnish any support. The new formations are true tumors, pure connective tissue growths originating from the submucous connective tissue. The giant cells, which resemble the tuberculous giant cells of Langhans, are proliferations of endothelia from the walls of small veins and the leucocytes also take part in their production. The fibrous connective-tissue stroma is the distinguishing feature between these tumors and a round-celled and spindle-celled sarcoma, in which the fundamental substance in sparse and more homogeneous or slightly granular. In one case described, the tumor consisted of cellular tissue of moderate vascularity, mostly round cells and young connective-tissue cells. Besides it contained a large number of partly rounded, partly elongated giant cells, with numerous processes and marginal nuclei, and at some places firmer tracts of connective tissue. The clinical proofs are the history and other syphilitic lesions. The best criterion for the diagnosis is the success of the anti-syphilitic treatment.

Distribution of the Ulcers in Typhoid Fever.—Joseph Louis Baer gives a review and discussion of the literature on this subject and an analysis of his series of eighty-nine cases. After presenting statistics, the writer states that several facts worth noting are brought into prominence. Probably the most striking among these is the wide distribution of the typhoid ulcers. They are found in every division of the alimentary tract excepting the mouth, and they are found also in the larynx and trachea. Gastric ulceration, though very unusual, is now regarded as quite possible in typhoid fever. The duodenum is the second rarest site for typhoid ulcers, only three cases being found. The low percentage of ulcers in the jejunum, $5\frac{1}{6}$ per cent., calculated from a total of 1,358 cases, confirms the general impression as to the infrequency of jejunal involvement. Involvement of the ileum is found in 89 per cent. of the cases. Ulceration of the small intestine in any part has been recorded in 97.5 per cent. of 623 cases. Ulceration of the common bile-duct is the rarest site for typhoid ulcers. One case is reported in a series of 439 cases. Involvement of the large intestine alone was not found in any statistics of the literature. In the present series, however, 5 cases were found. The one important factor in determining the seat of the lesions is the extent and character of the lymphatic apparatus of the part. Yet the frequent occurrence of pharyngeal and laryngeal involvement, indicate that accidental lodgement of the typhoid bacilli is another factor of considerable importance. The fact that there are many cases of typhoid fever without ulceration points to the existence of other possible factors, such as a lowered resistance of the gastrointestinal mucosa, which in these cases without ulcerations has reached its lowest ebb.

On the Surgical Importance of the Visceral Crises in the Erythema Group of Skin Diseases.—William Osler states that the possibility of mistaking these visceral crises for appendicitis or intussusception, or obstruction of the bowel and handing the patient over to the surgeon for operation, is by no means remote. The writer gives a short history of three cases in which laparotomy was performed and draws from them the following practical lessons: First, in children with colic, the greatest care should be taken to get a full history, which may bring out the fact of previous attacks, either of skin lesions, of arthritis, or of intestinal crises; secondly, there should be made the most careful inspection of the skin for angioneurotic œdema, purpura, or erythema. It should also be remembered that recurring colic may be for many years the sole feature of this remarkable disease; and the obscurity of the attacks of colic may not be cleared up till the final appearance of skin lesions. In one of the cases here reported, the intestinal crises, in combination with arthritis and the renal features, leave no doubt as to the diagnosis, The writer says that in the next attack there may be purpura or angioneurotic œdema, or an acute nephritis may occur alone. The colic is the most constant of the visceral manifestations, occurring in twenty-five of the twenty-nine cases in the author's series. It seems never to be dangerous. In no case recorded has death resulted from intestinal causes, according to the writer's belief.

Society Reports.

ASSOCIATION OF AMERICAN PHYSICIANS.

Nineteenth Annual Meeting, Held in Washington, D. C., May 10 and 11, 1904.

Dr. Wm. T. Councilman of Boston, in the Chair.

TUESDAY, MAY 10—FIRST DAY.

The President's Address.—Dr. Councilman, after welcoming those present, advocated the removal of limitation of membership, and also asked that membership in the association be limited to twenty years after which they would be placed as honorary members. In this manner at least seven new members could be acquired each year.

The Influence of Suprarenal Extract upon Absorption and Elimination with Demonstrations.—Dr. S. J. Meltzer and Dr. John Auer of New York presented this communication. A description of experiments to establish the retarding effect of suprarenal extract upon absorption and elimination was made by Dr. Meltzer. When adrenalin was given to frogs they rapidly became paralyzed, and this effect was not a muscular paralysis, for it could be demonstrated that stimulation of the sciatic nerve resulted in muscular contraction as occurred in normal muscles. The paralytic effect, therefore, was a central one. This same effect was shown in rabbits. If .6 mg. of strychnine was injected there followed a fatal effect of tetanic nature in from fifteen to twenty minutes; but if adrenalin was first injected there would be no tetanic effect at all, and this was explained by the delayed absorption. Further studies were made with some substance which was harmless to the animal, as fluorescin; this was injected subcutaneously into a rabbit, and after a few minutes the conjunctiva became yellow, the mucous membranes, the urine and the skin. When adrenalin was given it appeared considerably later, showing again delayed absorption. It was also proven experimentally that not only was absorption delayed, but also elimination.

Polyuria in Typhoid Fever.—Drs. M. H. Fussel, H. S. Carmany, and H. Hudson of Philadelphia presented a paper on this subject. A man, forty years old, was admitted to the hospital on the eighth day of his fever, April 15. The temperature ran the ordinary course. On May 7 it became and remained normal until his discharge. He was an extremely nervous individual. April 23 he had a slight intestinal hemorrhage. When he entered the hospital he had been getting 5 grains of salol every three hours, which gave rise to the presence of salicylic acid in his urine. He was bathed, but not tubbed, and was given eleven baths. The first twenty-four hours after his admission he passed 1200 c.c. of urine; the second, 1,500 c.c.; the third, 7,000 c.c.; the fourth, 7,200 c.c., and then it dropped to 3,500 c.c., where it remained for some time. The polyuria really was a complication of the disease because it disturbed him so much. The skin was dry, and he was very restless. One year after this attack he was examined again, and the urine was found to be normal.

Polyuria in Typhoid Fever.—By Dr. James C. Wilson of Philadelphia (read by title.)

Dr. George Dock of Ann Arbor, Mich., said that the elimination of water in typhoid fever in the beginning was but little, there being actually a retention of fluid within the body; soon after the amount of fluid excreted was increased, until at last there was a polyuria; observations he had made confirmed this. He thought that a later diminution in the excretion of the urine could be explained by the weakening of the heart's action and a lowering of the blood pressure.

Dr. William Osler of Baltimore said that polyuria that occurred in tuberculous peritonitis, in retroperitoneal tumors, in aneurysm of the abdominal aorta, etc., might be the result of local irritation.

Dr. Fussell, in closing the discussion, said that the more water that was discharged the less hysterical the patient seemed to be.

Cases of Venous Thrombosis Occurring in the Course of Typhoid Fever.—Dr. W. S. Thayer of Baltimore read this paper. He said that his observations were taken in Dr. Osler's wards at the John Hopkins' Hospital, and out of 1,462 cases of typhoid fever there were 39 instances of venous thrombosis, or 2.6 per cent. In 5 of these 39 cases a fatal result was recorded. The lower extremity was the seat of the thrombosis in all but a very few of the cases. In 21 instances the thrombosis was in the femoral vein, popliteal vein in 5, iliac vein in 5, in the calves of the leg 5, in the saphenus vein 3, etc. In 36 cases the development of the condition was associated with fever; in 3 there was none. In 26 cases the fever was intercurrent; in 13 the temperature was normal at the time the thrombosis was first noticed. In 11 of the 39 cases the complication was associated with chill. The first distinct symptom was pain, and, in the instances of femoral thrombosis the pain was along the course of this vein. In 22 of the cases a leucocytic count was made, the highest recorded being 24,864; this was in a case of iliac vein thrombosis occurring during the third week of the disease. The lowest was 2,700, and this occurred on the day after the onset of the thrombosis. In all of the instances there was more or less prolonged disability. In 6 cases there was œdema lasting several weeks and longer; in 4 there was severe cramps in the legs; in 1 the patient complained of severe pain in the leg and thigh, especially after standing. The following brief conclusions were drawn; In 28.2 per cent. of the cases the venous thrombosis was associated with chills, and, in most of the cases, there was an increase in the leucocytic count, depending upon the extent of the lesion. In cases of sudden severe pain in the lower part of the abdomen and associated with leucocytosis the possibility of iliac thrombosis should be carefully considered. He emphasized the fact that thrombosis of the veins of the lower extremity was a very serious condition, and the after-results should not be lost sight of. Marked varicosities may be present and lead to more or less permanent disability, as illustrated in a photograph he showed.

Dr. George L. Peabody of New York referred to the giving of calcium salts to increase the coagulability of the blood. This coagulability of the blood could be diminished and the likelihood of thrombosis lessened by administering citric acid which reduces the solubility of these salts.

Dr. Alfred Stengel of Philadelphia said that at times the general symptoms preceded the local signs. He referred to one case; this patient entered the hospital in the convalescent period with a marked septic fever, temperature reaching 106 or 107°, decided chills and sweating, without there being any local symptoms whatever. The leucocyte count was 7,000. The general appearance of the patient, the emaciation, the absence of leucocytosis lead to the tentative diagnosis of post-typhoidal thrombosis.

Dr. William H. Welch of Baltimore said that the French school favored the old view that these cases were of primary origin due to infection of the venous walls and subsequently a phlebitis. Importance was also placed upon the increased pulse rate as an important sign.

Dr. W. Gilman Thompson of New York said he had under observation eight cases of femoral thrombosis, all these patients having suffered from general weakness and œdema for from six to ten years.

Dr. James Tyson of Philadelphia ascribed the pain accompanying thrombosis to vascular obstruction, such as occurred in angina pectoris and in cramps in the calves, etc.

Dr. William Osler of Baltimore spoke of the difference between phlegmasia dolens after puerperal fever and the thrombosis of typhoid fever. In the latter, one might

may, it gave the typical picture of post-partum phlebitis, with the swelling, the white color, the pain which may or may not be localized but not extremely agonizing, as in post-puerperal cases. He did not believe these cases were quite as severe as ordinarily stated. He had known of several cases in which recovery was complete and the circulation established. He believed that the patients with femoral thrombosis should blame their parents because the thrombosis depended upon the venous arrangement: if a man was well put together and had a well-arranged venous circulation, he could have a femoral thrombosis and yet recover with a good circulation.

Clinical Studies in Arteriosclerosis.—Dr. ALFRED STENGEL of Philadelphia read this paper. He considered the blood-pressure conditions in both the early and in the later stages of arteriosclerosis. The blood pressure was ascertained by means of an instrument devised by Dr. Stanton, and was of value in that it recorded both the diastolic as well as the systolic pressure. Systolic pressure in arteriosclerosis was not necessarily high, but the diastolic blood pressure was always high until that time when the myocardium was diseased and failed. Therefore, the diastolic blood pressure was the most imporant factor to determine in this disease. Sustained pressure was, of course, more characteristic. He next spoke of the blood changes, contrasting them with the appearance of the patient. He said that all knew the arteriosclerosis facies, the pallor, etc., which appeared rather rapidly. He had seen cases with such changes that made him suspect malignant disease. In examining the blood of these people one always finds unexpectedly a high blood count. Whether this was due to inspissation of the blood or to the same cause that was effective in producing European tropical anæmia, was a question he could not answer, although he favored the latter view. The condition of the urine showed a great variability in the amount excreted and in the specific gravity. Sustained systolic blood pressure and sustained first heat sound were considered. He said that one of the first evidences of cardiac sclerosis was a sustained and prolonged character of the first heat sound before the myocardial degeneration appeared, and this was a very important point in determining the early development of arteriosclerosis.

Dr. S. SOLIS COHEN of Philadelphia said that many factors were involved in the estimation of the blood pressure in these cases. In his own clinical observations he said he was inclined to lay great stress upon the prolongation and impurity of the first sound. Regarding the condition of the urine, he had not only found changes in the specific gravity but also in the toxic content.

An Investigation of the Effects of Cardiac Stimulants, Especially Strychnine, on the Blood Pressure in Febrile Conditions.—Dr. R. C. CABOT of Boston considered this subject and gave the measurements of the maximum and minimum blood pressure made with the Stanton modification of the Riva Rocci instrument in febrile cases before, during, and after the administration of strychnine both by mouth and subcutaneously. Among these cases were 31 of typhoid fever, 4 of pneumonia, and 15 with a variety of diagnoses. Over 5,000 measurements were taken and the total results were negative. One-eighth to one-sixth of a grain of strychnine were given, careful records were taken, and all with negative results. The emotions caused by the sight of a friend, by the sight of food, etc., caused as great an increase in the blood pressure as did the drug.

Dr. ALFRED STENGEL of Philadelphia said that the results obtained by Dr. CABOT substantiated the views of the French school, that this increase in the blood pressure was a vasomotor disturbance; this was shown by the increase in it through certain emotions.

Dr. HOBART A. HARE of Philadelphia said that strychnine was not a cardiac stimulant, although the profession in general used it as such, as they used to give digitalis. All must be convinced that the drug was much abused in typhoid fever, in pneumonia, and in diseases in which stimulation was greatly desired. Strychnine did not act in the sense that it increased the force of the circulation; he thought it acted simply as an irritant and produced its effect upon the nervous system akin to whipping a horse.

A Supposed Cause of High Tension Pulse in Nephritis.—Dr. WM. H. THOMSON of New York read this paper, in which he stated that a high tension pulse occurred too early in nephritis to be due to any other cause than the presence in the blood of a general vasoconstricting agent similar in its properties to adrenalin, and that such an agent would also produce constriction of the renal vessels and general shrinkage of the kidneys, causing interference with the excretion of urea. Prolonged presence of such an agent in the blood would lead ultimately to endocarditis with degeneration of the vascular walls and to cardiac changes. Acute cardiac dilatation may occur from the effects of such a general vasoconstricting agent in the circulation before extensive alterations in the blood-vessels had taken place. Aconite he considered to be the best vasodilator in nephritis, much more effective than the nitrites. Reports of marked increase in the excretion of urea followed its administration.

Dr. GEORGE L. PEABODY said that his own experience showed that there was no doubt regarding the effects of aconite, even when there was an abnormally low-tension pulse, to frequently increase the urea output.

Poisoning by Illuminating Gas—A Clinical Study of Ninety Cases.—Dr. W. GILMAN THOMPSON of New York read this paper. After referring to the comparatively few cases recorded in the literature, he summarized as follows:

1. Leucocytosis was both high and persistent, rising in many cases above 18,000 and, in a few fatal cases, as high as 50,000. A differential leucocytic count showed a preponderance of the polymorphonuclear cells. A high degree of leucocytosis was a very unfavorable sign.

2. The elevation of temperature was observed in nearly all the cases. The fever was usually moderate and of very irregular type. In many cases a subnormal temperature preceded the elevation, and it was often observed also in convalescence. The pulse was disproportionately rapid as compared with the temperature.

3. The nervous symptoms were both varied and inconstant. Convulsions occurred in about 7 per cent. of all cases and muscular rigidity in a slightly larger proportion. The reflex and pupil symptoms showed great variability. The coma bore no definite relation to the intensity or duration of the fever. Coma lasting four or five days was not invariably fatal. In the series of ninety comatose cases only 17 or 18 per cent. were fatal.

4. The result of combined phlebotomy and saline infusion justified this prompt and thorough employment of these measures.

5. Pneumonia was an infrequent complication, and, in a large percentage of fatal cases, the cause of death could be referred to cerebral lesions, such as congestion of the meninges and brain substance, hemorrhage of the cerebral capillaries, or hemorrhage into and softening of the internal capsule, lenticular nucleus and adjacent structures.

Dr. ALFRED STENGEL of Philadelphia said that a few years ago Darrah made a series of experiments in resuscitating animals poisoned by illuminating gas, and he found that they could not be brought to and saved by saline transfusions. The combination between the gas and the hæmoglobin was so close and the attempted disassociation so slow that the animals died before the poison was eliminated.

Dr. GEORGE L. PEABODY of New York said that defibrinated blood for use in such cases was logically all right, but was very difficult to get when needed. The use of oxygen in these cases he considered to be absolutely useless. He referred to one case in which the coma existed for four weeks with recovery of the patient.

Dr. FRANCIS P. KINNICUTT of New York said that neither the depth nor the length of the coma should be taken as indications upon which to base the prognosis. He spoke of the phenomenon of seeing cases of illuminating gas poisoning with beautiful ruddy red color.

Dr. HOBART A. HARE said that oxygen to be effective in these cases should be administered pure as possible. Regarding defibrinated blood, not only was it difficult to obtain when needed, but also it was an objection to introduce the blood of one man into the circulation of another.

Dr. S. SOLIS COHEN of Philadelphia said that there were other gases besides carbon monoxid to consider when speaking of illuminating gas which varied both in quantity and in kind and belonged to the hydrocarbon series.

Before the adjournment of the morning session Dr. S. WEIR MITCHELL read a communication from Noguchi, who was in Copenhagen carrying on experiments with snake venom. This Japanese was associated with Dr. Mitchell and Dr. Flexner, and drew attention to himself by his good and able work. The attention of the Carnegie Institute was called to him, and he received from it enough money to enable him to go abroad to continue his work in the line of investigation. This fostering of scientific research, when effective and good men were found, was much encouraged, and this letter from Noguchi was loudly applauded.

Abdominal Pain from Unsuspected Irritation of the Internal Inguinal Ring.—Dr. CHARLES G. STOCKTON of Buffalo presented this communication, and reported twelve cases in which abdominal pain occurred as the result of irritation at the inte nal inguinal ring, dependent upon very slight protrusion of the hernial sac into the inguinal ring. The cases were believed not to be uncommon, and were sometimes perplexing and often misinterpreted. As a rule the pain followed exercising, but in one case it appeared when the patient was at rest. Such cases should be understood, otherwise they may be taken for cases of appendicitis and other visceral troubles. These cases could be relieved by proper support by truss.

Dr. GEORGE L. PEABODY of New York related the case of a physician who had attacks of severe pain in the lower half of his abdomen which was intermittent in character. He was found to have a patulous inguinal ring and the application of a well-fitting truss relieved him.

Dr. GEORGE DOCK of Ann Arbor related a case illustrating the fact that at times pain in the abdominal region may be felt far away from the seat of the disease.

The Mechanism of Exophthalmos.—Dr. W. G. MACCALLUM and Dr. W. B. CORNELL of Baltimore presented this paper. The question existed as to the mechanism by which the exophthalmos which appeared in the dog on stimulation of the cervical sympathetic was produced. Certain authors held it to be due to distension of blood-vessels in the orbit, others to contractions of smooth muscle fibers about the eyes. Experiments showed that obstruction to the outflow of blood caused only an insignificant protrusion, and that the results of sympathetic stimulation were independent of any connection of the head with the circulatory apparatus. Direct observation showed that the exophthalmos was produced by the peristaltic contraction of a cone of tissue containing smooth muscle fibers which surround the eyes.

Diabetes Insipidus.—Dr. THOMAS B. FUTCHER of Baltimore took up the consideration of this subject and said that in seven out of nine cases observed in the wards of the John Hopkins Hospital were on the medical side and represented .03 per cent. of all cases therein. The cases he divided into two groups, (1) the primary or idiopathic, and (2) the secondary or symptomatic. The disease was more common in young individuals, the majority being between the ages of twenty and thirty years. Heredity was an important causative factor. It was more prevalent among males. Lesions of the brain seem to produce the disease in the majority of the cases. Diabetes insipidus may follow hemorrhage, hydrocephalus, basilar meningitis, or tumors at the base of the brain. Four out of the nine cases were due to lues, and polyuria and polydypsia were, symptoms, too, of cerebral syphilis. Syphilis as an etiological factor in diabetes insipidus was emphasized.

Dr. BAUMGARTEN of St. Louis reported a case of polyuria lasting for nine months when sugar then was first found. This patient died of tuberculosis of the lungs.

Dr. JAMES TYSON of Philadelphia said that he had been called in consultation to see as many as six or seven cases of diabetes insipidus, and the most interesting feature was that they were all largely relieved by the administration of iodide of potassium. He never knew of a case in which the patient died, although two or three that seemed to have recovered passed from observation.

Dr. GEORGE DOCK of Ann Arbor spoke of the cheery prognosis that could be given these cases with a syphilitic history.

Dr. A. JACOBI of New York said that the large majority of such cases were found in young children, and, as a rule, were not seen in the general hospitals. He had seen a number of cases in which the cause appeared to be the result of an anæmia, or chorea, or following attacks of chorea minor. He had also seen it follow whooping-cough in which it was attributed to cerebral hemorrhages. He had seen it result as the direct result of falls upon the occiput in boys from seven or eight to thirteen years old. In these cases, too, it might be dependent upon tumors.

A Case of Prolonged Male Hysteria with Autopsy.—Dr. S. WEIR MITCHELL of Philadelphia gave a full report of a case of hysteria occurring in a man which lasted some thirty years, followed by a post-mortem examination which gave only negative results.

Dr. PRINCE of Boston reported an analogous case.

Some Unusual Forms of Acute Myelitis.—Dr. B. SACHS of New York read this paper. He said that in the discussion that had been carried on for years regarding acute myelitis, doubt had been expressed as to the occurrence of acute myelitis if all cases due to syphilis, to traumatism, and to infection were excluded. There was no doubt, however, that there were some other forms which could not be conveniently described under any other term. Special account was taken in his paper of a senile form which would appear to be a spinal counterpart of the cerebral apoplexies occurring during the senile period. The tissue changes in this case could be attributed only to disease of the spinal blood-vessel. The paper also included the record of a very sudden development of myelitis in a young girl who, shortly after the onset of the myelitic symptoms, developed multiple streptococcic abscesses. The case was very remarkable because of the severity of the symptoms and on account of the partial recovery that had taken place. The first abscess appeared in the gluteal region and spinal caries was first thought of. Within twenty-four hours multiple abscesses developed all over the body, and they developed almost simultaneously with the myelitis. She was now a chronic paraplegic.

Infectious Neuritis with Report of a Case.—Dr. JAS. J. PUTNAM of Boston reported cases he had seen in consultation and at the Massachusetts General Hospital. One case was thirty years old and resulted fatally after eight weeks' duration. Sensory and motor symptoms were present, there was a constant fever and a leucocytosis of 33,000. The paralysis progressed slowly and went upward until it involved the bulbar area. Post mortem showed in general a disintegrated condition without vascular changes. In another case the paralysis spread in somewhat a similar manner. The face became involved and swallowing became very difficult. Fever was constant. The spleen was not enlarged. This case ended in recovery and was believed to be a case of multiple neuritis.

The Clinical Features, Prognosis, and Treatment of Cerebrospinal Meningitis in Infants and Children.—Dr. HENRY KOPLIK of New York read this paper. The ma-

terial collected in five years' hospital service numbered 89 cases of meningitis as follows: Forty-nine cerebrospinal, 39 absolutely confirmed by puncture, 35 tuberculous cases, 1 staphylococcocci, 1 streptococci, 1 pneumococci, and 2 were the so-called pseudo-influenza cases. Sixty per cent. of the cases were below the age of 2 years, the youngest being 4 weeks, the oldest 14 years. The average age among the tuberculous cases was about 4 years. He said the type cases in New York were the same as those of Councilman, Osler, Hirsch, Herrick of Chicago, and others. In one case the meningococcus was found in the conjunctival secretion. The clinical types were malignant, acute and subacute and basic. The mode of onset was sudden, as a rule, except in the tuberculous. Neck rigidity was always present at some period of the disease. The reflexes, if present at the beginning, may disappear toward the close. Babinski's reflex was present in 17 cases of cerebrospinal and 26 of the tuberculous, about 77 per cent. Kernig's reflex was of little utility below the age of 2 years. Myotonica congenita was present in all such cases. In the cerebrospinal cases hyperæsthesia was present in 62 per cent. Macewen's sign, in the 17 tuberculous cases it was present in 11; in the cerebrospinal it was present in 2. The temperature was of the prevailing type. The skin showed the rashes of some sort always present, but not so much so as in adults. Herpes labialis infrequently was found. Conjunctivitis was common. Optic neuritis was very uncommon. The disk changes were common in the tuberculous type, about 77 per cent. Of 20 cases 7 showed tuberculous choroiditis. In the cerebrospinal form the leucocytes were from 20,000 to 55,000, exceeding 25,000 in 55 per cent. of cases. In the tuberculous cases 40 per cent. ran from 20,000 to 25,000. They were under 20,000 in 60 per cent. of the cases. Regarding the mortality, of the 49 cerebrospinal cases the death rate was 36.7 per cent.; of the absolute cases, 41 per cent. The disease he believed to be self-limited and not influenced by any mode of treatment. The varying mortality was about 62 per cent. and 25 per cent. Lysol injection treatment, 31 cases, 18 recovered, or 42 per cent., but this treatment did not prevent relapses. In his own cases lumbar puncture was not curative, nor did it prevent relapse or rise of temperature, nor did it relieve the headache and symptoms of pressure.

A Case of Spasmodic Stricture of the Œsophagus with Sacculation, Treated by Dilatation, and Later by Gastrostomy.—Dr. JAMES TYSON, Dr. EDWARD MARTIN, and Dr. THOS. EVANS of Philadelphia presented this communication. The patient was a man, thirty-three years old, who had suffered from dysphagia since he was twelve years old. At that time he was suddenly seized with dysphagia while eating his supper and regurgitated his food. For fifteen years he fed himself with great difficulty, taking solid food first and following it with large quantities of liquid. He was first examined by Dr. Tyson in 1895, and on attempting to pass a tube it bent upon itself when at the seat of obstruction. When the œsophagus was washed out a large quantity of mucus was obtained. The absorption and motor power of the stomach was good. He saw the patient again in 1903 when the condition was about the same. A floating kidney was then noticed and a slight gastroptosis.

A second case was reported in which the patient had been under observation two and a half years. The patient was a woman, thirty-three years old, with good family history and no tendency to neurotic conditions. Not much benefit being obtained from ordinary treatment, Dr. Martin saw her in consultation and advised dilatation and paralysis of the cardiac orifice by an apparatus of his own device. Dr. Martin thought he would have succeeded in this treatment had it been persisted in. Later a gastrostomy was done and the patient died soon after.

Idiopathic Dilatation of the Œsophagus; Cardiospasm.—Dr. B. W. SIPPY of Chicago presented an anatomical specimen which was rare. The patient from whom it was taken was a woman, thirty-three years old, who gave symptoms of œsophageal obstruction for five years. She often would have to leave the table to regurgitate what she had eaten. The globus hystericus was present. Lost a great deal of weight, and symptoms soon became aggravated. In the hospital it was decided that she was suffering from pyloric obstruction and a gastroenterostomy was performed. This was followed by some betterment of her condition for one week when she returned to her old condition and she finally died. The œsophagus normally would contain 100 c.c. of fluid, but the one removed contained 500 c.c. There was a fusiform dilatation and an enormous hypertrophy of the walls of the œsophagus, especially at the point where dilatation was the greatest.

Dilatation of the Œsophagus and Stomach.—Dr. FRANCIS P. KINNICUTT of New York presented this enormously dilated œsophagus which was a record breaker, so far as he could learn, in that it contained 1,800 c.c. of fluid.

WEDNESDAY, MAY 11—SECOND DAY.

The Relation of Cells with Eosinophile Granulation to Bacterial Infection.—Dr. E. L. OPIE of Baltimore read this paper. The guinea-pig was the most suitable animal for the experiments made. Bacteria causing fatal affections, he said, gradually diminished the eosinophiles, and charts were shown to illustrate the effects of various bacteria upon eosinophile cells. The appearance of the eosinophiles in the tissues was in harmony with their disappearance from the blood. The influence of these and their severity in fatal affections suggested to him the desirability of studying their behavior during the course of acute affections from which animals were capable of recovering, and, in making the tests, the peritoneal cavity was believed to be the best because the fluids could so readily be obtained therefrom. During the course of pneumonia, typhoid fever, various pyogenic and other infections, eosinophile leucocytes disappeared in part or wholly from the peripheral circulation. Injections of a variety of bacteria into the peritoneum of guinea-pigs caused a similar disappearance of these cells, followed after a few days, should the animal survive, by an increase above the normal. Examination of the mesentery during the height of infection demonstrated that eosinophile leucocytes collected in its blood-vessels, and hence migrated into the peritoneal cavity in company with the more numerous finely granular leucocyte. Eosinophile leucocytes, he said, collected in considerable number upon the surface of the omentum and here underwent degenerative changes. That eosinophile cells were profoundly affected by bacterial poisons was further shown by the accumulation of eosinophile myelocytes in large number in the spleen only four hours after inoculation. Eosinophile leucocytes had a part in the inflammatory process which followed bacterial invasion. He said that they rarely acted as phagocytes, but that they really did have a part in the bacterial invasion.

Dr. Opie said that there really was a contrast between animal parasites and bacteria, and a very marked similarity. Trichinosis caused a leucocytosis which was in part due to the increase in the eosinophile cells and in part to an increase in the ordinary polynuclear or neutrophiles. The first effect of bacteria caused a diminution in the eosinophile cells, but, as shown by certain studies, there was subsequently an increase in them if time was given for them to increase. Therefore, increase in the eosinophiles occurred with bacterial invasion when recovery occurred. It seemed to him that the toxins of the animal parasite and the bacterial toxins were chemotaxic for both forms of parasites.

A New Case of Chloroma with Leukæmia, with a Study of the Cases Reported Since 1893.—Dr. GEORGE DOCK and Dr. A. S. WARTHIN of Ann Arbor, Mich., presented this communication. Eleven years ago a condition was

described by Dr. Dock which was characterized clinically by pain and anæmia without evident cause, loss of strength, hemorrhages in the skin and elsewhere, rapid pulse, pain in the eyes, difficulty of vision, strabismus, and exophthalmos without any special symptoms of Basedow's disease, with ringing in the ears and tumors appearing in the temporal region, etc. In three out of the nine cases observed since 1893 there was an increase in the leucocytes. He reported an additional case, as follows:

A man, aged forty-five, without reasonable cause, began to get extremely weak, so much so that he had to take to his bed at times. His pulse was very rapid. The course of the case resembled very closely one of pernicious anæmia. After being ill for one year he came under the doctor's observation. There was no absolute enlargement of the lymphatic glands, the leucocytic count was 35,000 and the picture was quite marked of lymphatic leukæmia in the blood. He lived for several days. At autopsy green tumors were found along the front of the vertebræ, both sides of the sternum and around the origins of muscles, in the kidneys, liver, and lungs. The blood counts were given. Only a partial autopsy was obtainable. There was nothing indicating any chloroma of the head before death, and a clinical diagnosis was made of an acute leukæmia. No advanced lesions in the stomach or intestines were found. Before autopsy Dr. Dock decided that he had to do with a case of chloroma. He said that since 1893 twenty-one cases had been reported, more or less fully, and the disease was apparently not so rare a believed. During the past year he knew of half a dozen cases that had been published. The disease preponderated greatly in the male. The average age was 18.8 years, most of the cases being below twenty years of age. He regretted that the peculiar green tumors could not be examined in all cases. Usually they affected the base of the skull or in the sinuses in the vicinity. A great many were found in the temporal fossa They also occurred in the orbit, causing the exophthalmos. In thirteen of the cases the picture of the blood was that which characterized a leukæmia. In two of the cases there were over 300,000, in another over 500,000 leucocytes. In another case the leucocytes were less than 100,000. The blood picture on the whole was that of an acute lymphatic leukæmia; in some it appeared like the myelogenic form. It was remarkable that nothing was known regarding the color; chemical and other tests of this green color had availed nothing so far as determining what it was. Regarding the pathological diagnosis there was a great variance of opinion.

Dr. Dock then presented Dr. Warthin's conclusion. The latter had attended to the anatomical part of the investigations. Chloroma belonged to a group of lymphomata. It was primarily a tumor-like hyperplasia. Chloroma, associated with myelogenous cells, was undifferentiated; these cells readily break down, and so accounted for the early changes in chloroma, and in some cases of leukæmia; this too explained some of the blood findings in the differentiation.

Dr. MELTZER of New York said the picture reminded him of myeloma confined to the bones of the trunk.

Dr. DOCK, in closing the discussion, said that many of these cases of acute leukæmia, especially with scorbutic type, might be as severe as some cases of chloroma. The cases were sometimes very severe in their course, and depended upon deficient blood formation. Most of the cases gave the picture of acute leukæmia, the disease ran for four or five months, and then ended with scorbutic symptoms. The general picture was not different from that of leukæmia. In no case were the bones thoroughly examined because of the difficulty in obtaining consent. With regard to myeloma Dr. Dock wondered what was meant by that term.

Types of Splenic Anæmia or Splenomegaly.—Dr. ALFRED STENGEL of Philadelphia read this paper and reported three cases with microscopic studies:

CASE I. The first case was a child two years and three months old whose personal and family history were good. When twenty months old the parents noticed an increase in the size of the abdomen and increasing pallor. There were slight signs of rickets. This child came under observation with an enlarged spleen and remained under observation for a number of months. The blood count showed 2,920,000 red cells, 30 per cent. hæmoglobin, 7,600 white cells. Subsequently the child became dropsical and developed a leucocytosis, 15,000 to 20,000 leucocytes to the cm. The child died, and at autopsy there was discovered a uniform spleen enlargement, with infarctions comparatively recent in both spleen and kidneys. There was also a vegetative endocarditis of the mitral valve, a bronchopneumonia, and miliary tuberculosis affecting the lungs, spleen, and liver. There was a diffuse fibrous growth of the spleen and some, but not marked, proliferation of endothelial cells. The infarctions presented an ordinary appearance. The lymphatic glands showed a marked hyperplasia, necrosis of endothelial cells of the lymphatic sinuses, the red cells in these sinuses being quite peculiar. There was also an enlargement of the terminals of the portal vein.

CASE II. This patient was under observation for three years. No syphilitic or malarial history could be obtained. There was cirrhosis of the liver and pigmentary changes in the skin, clubbed fingers, and stunted growth. The hyperplastic changes in the spleen and the hepatic cirrhosis were very marked. There were also fibroid changes in the lung and other organs. There was a hypoleucocytosis. The bacteriolytic qualities of the blood serum were found to be normal.

CASE III. This was a case of primitive splenomegaly occurring in a young adult woman, twenty-five years old. She was supposed to have had an ovarian tumor. She had had two miscarriages. She gave no history of previous illness. For five or six years she was conscious of a mass in the left side of the abdomen which caused her great discomfort. Splenectomy was advised and performed. She then developed a pneumonia and was still under observation. An examination gave practically the same figures as in the first case. Sections of the spleen were shown and revealed tremendous solidity. Upon cross section it was seen to be invaded by some neoplastic growth. There were no evidences of necrosis and no tubercle bacilli could be demonstrated. No bacteria could be found with the Gram stain. Nothing could be found of a protozoon nature. It was suggested that there was some form of an infective process which caused the growth. The possibility of syphilis as a causative agent he thought could be excluded in this case. He referred to the great tendency of attacks of infectious nature occurring, such as an orchitis, cellulitis, etc.

Dr. WILLIAM OSLER of Baltimore thought that such cases should be sent to the surgeon more frequently. He had nine cases of great enlargement of the spleen with anæmia under observation since his last paper on this subject. One case was a primitive splenomegaly and the only discomfort was attributed to the enlarged organ. There were four cases of chronic splenic anæmia, enlargement of the spleen extending over many years. There was also a leucopœnia of moderate degree and pigmentation of the skin. He believed these cases should be more carefully studied.

Dr. GEORGE DOCK of Ann Arbor, Mich., said that we should be doing more in an operative way in these cases. He said there were a large number of splenic diseases which seemed to have an effect of destroying the blood and also causing destructive processes in the liver, and these were the cases which should be operated upon successfully. In all cases with enlarged spleen one should be careful to exclude such conditions which negative the operation. By operation and getting the spleen and saving the abdominal organs early he said we were bound to get such an increase in our knowledge as could not be gotten in any other way.

Dr. B. W. SIPPY of Chicago reported an instance of

enlarged spleen extending below the umbilicus, freely movable, which presented a picture of a gradually developing anæmia. The blood count showed 2,460,000 red cells, 40 per cent. hæmoglobin and 4,200 white cells. Splenectomy was performed and the patient has done very well since operation. He thought that the anæmia was due to a splenic hyperplasia and certain changes in the blood which produced substances which caused malnutrition. The examination of the spleen showed an ordinary splenic hyperplasia. There were no evidences of cirrhosis of the liver or enlarged lymph nodes.

Dr. R. C. CABOT of Boston spoke of the possibility of the case being due to malnutrition and said that there were no evidences, clinically or experimentally to prove that anæmia was due to malnutrition.

Dr. WILLIAM OSLER of Baltimore referred to the importance of looking for the Donovan-Leischman bodies, which he thought would soon be imported here from tropical countries, especially Manila.

Dr. ALFRED STENGEL, in closing the discussion, stated that the young woman was apparently in excellent health and malnutrition was not the basis of her difficulty. Repeated examinations had been made for the tubercle bacilli, but in vain.

On the Cultivation of Trypanosoma Evansi.—Dr. F. G. NOVY, Dr. W. J. MCNEAL, and Dr. C. B. HARE of Ann Arbor, Mich., presented this paper which approached the question of the identity of the *surra* of the Philippines with the *nagana* or the *tsetse-fly* disease of South Africa. It was shown that the trypanosome present in the Philippine *surra* could be cultivated artificially and also that it could be obtained in an attenuated form. The cultural characteristics of this trypanosome differentiated it clearly from *Trypanosoma lewisi* and *Trypanosoma brucei*, and the conclusion was, therefore, reached that the Philippine *surra* was a distinct disease, different from *nagana*, and confirmed that of Laveran and Mesnil, based on immunity experiments, as to the non-identity of the *surra* of Mauritius and Nagana. In these experiments they took rats which had become infected in barnyards and by combining artifical media, such as agar agar and defibrinated rabbit's blood, they were able to continue their work. The cultures grew not on solid agar, but in the water of condensation. Their first successful results were obtained in May, 1902, and at the present time, after two years, these cultures had been carried on to the thirtieth generation. One year ago last December another series of cultures were grown at 34 to 37 degrees in incubators and it was found that they grew rapidly and died quickly, so much so that it was necessary to transplant them every week. In 18 months they had succeeded in obtaining 65 generations. Success in this work had caused them to enter upon a wider scope. Last June they secured living mice inoculated with the South-African disease and the new series of cultures begun. The *Trypanosoma lewisi* grew readily but the South-African parasite grew with difficulty, which made further investigation a difficult undertaking. Yet from the first they were able to keep the organism alive for 18 days in media in test-tubes. Comparing with the *Trypanosoma lewisi* it was soon found that there had actually been picked up a stray rat trypanosome. The rat had been inoculated with the South-African parasite which previously had been inoculated with the rat trypanosome from which he had recovered, showing no trypanosomes in the blood for a period of three months. Then when he was inoculated with the South-African parasite and died, the *Trypanosoma lewisi* and not the *Trypanosoma brucei* was obtained from the blood. At last he succeeded in getting a positive evidence of growth in 8 out of 100 cases, or 8 per cent. Since then he had made attempts at finding a better media which would give a larger percentage of successful cultures. It was an interesting point that cultures that develop at the room temperature of 25 degrees, were virulent when injected into rats, mice, or guinea-pigs. Again if the material was placed in an incubator for two days at 34° C. the organism remained alive and active and apparently healthy, but when introduced into an animal produced no effect. He realized that there was an attenuated form of pathogenic protozoon.

The Agglutination and Filtration of Trypanosomes.—Dr. F. G. NOVY and Dr. W. J. MCNEAL of Ann Arbor, Mich., presented a paper on this subject and stated that the presence in cultures of *Trypanosoma lewisi* of actively motile, minute forms, ranging from 2 to 5 microns in length, suggested the possibility of passing the organism through a Berkefeld filter. Of nine experiments made with cultures of this organism three were positive, five were negative, and one was uncertain since the control animal failed to develop infection, Similar experiments with cultures of *Trypanosoma brucei* and with the suspensions of organs of animals infected with the latter gave negative results. It would seem as if some "filterable diseases" might be due to organisms which themselves were so large as to be incapable of traversing a filter, but which, under certain conditions, would give rise to a minute stage which would pass through the filter.
